TABLE OF CONTENTS

THESIS ABSTRACT

Direct PCR is fast becoming a popular method in forensic science due to the advantages of saving time and money in the laboratory while increasing the probability of obtaining substantial results has a positive rippling effect. A laboratory is able to reduce the time spent on processing trace DNA samples, which can lead to investigators receiving important information in a timely manner that may not have been possible using standard methods. DNA extraction procedures are standard practice in the initial steps of DNA profiling when examining swabs, adhesive tapes and sections of fabric. Significant loss of DNA can occur during this process resulting in no DNA profile generated. Direct PCR circumvents the extraction process such that a DNA profile may be generated directly from the substrate. This saves time, increases the DNA yield, reduces tube changes, and minimises steps open to error or contamination in the laboratory.

To fully understand the benefits and limitations of direct PCR, several aspects of the method have been analysed in this thesis. The loss of DNA via extraction was investigated and determined for the most common extraction methods used in forensic science, as well as understanding the limit of detection for the commerical PCR human identification kits. From this, a statistical method to quantify the DNA template used in direct PCR amplifications based on the resulting magnitude of the allele peaks generated was developed. In this PhD study, trace evidence items investigated using direct PCR include: human hairs, canine hairs, fibres, human finger nails, and human teeth. Substrates have been analysed using both short tandem repeat (STR) and single nucleotide polymorphism (SNP) methods for identification. A high level of succesful profile generation has been found across all of the substrates. A successful profile produces five or more complete loci that can be up-loaded to the National Criminal Investigation DNA Database (NCIDD, Australia).

Current practice for many laboratories is that trace evidence items, such as the ones listed above, are generally not subjected to DNA testing as there is little chance of generating a meaningful DNA profile. All direct PCR methods, where applicable, have followed validated protocols as to maintain high standards and allow fast implementation within forensic laboratories. The only alteration to the PCR methods was an increase in the amount of DNA polymerase used to help overcome any potential inhibitors present on the substrate. This study highlights direct PCR sensitivity and the ability for trace DNA to be amplified without the need to increase cycle number or modify current protocols to obtain meaningful data. Based on the data presented in this thesis, a direct PCR approach is a viable option for the future of trace DNA recovery and analysis for forensic science purposes, vastly improving efficiency, sensitivity and the quality of results.

DECLARATION

I certify that this thesis does not incorporate, without acknowledgment, any material previously submitted for a degree or diploma in any university; and that to the best of my knowledge and belief it does not contain any material previously published or written by another person except where due reference is made in the text.

ACKNOWLEDGEMENTS

I would like to express my deepest appreciation to my supervisor and mentor, Professor Adrian Linacre, for his continual guidance, teaching, patience and support throughout the years. He has taught me invaluable lessons about the world and history of forensic science and what it truly means to be a critical thinker, to always push the boundaries of what may seem impossible. For this I will be forever grateful.

Thank you to my co-supervisor Dr Duncan Taylor of Forensic Science SA for his extended support, advice, and encouragement as well as providing undeniably insightful feedback on all of my work. With his help and guidance, statistics actually seemed enjoyable and somewhat understandable! I could not have imagined two better mentors to guide me through this Ph.D adventure.

To the many amazing people I have met at Forensic Science SA and through attending conferences, thank you for taking time out to listen, teach, and provide me with advice and opportunities. I feel honoured to be a part of such a wonderfully helpful forensic science community and family. Thank you to the Attorney General's Department of South Australia for their continued financial support of our laboratory and this project.

To all of my Flinders DNA labmates and office monkeys that have come in and out of room 2003 over the last few years – you have all been such a treasure to be around, learn from and laugh with. A special thank you to my saviours of sanity: Jennifer Templeton, Sherryn Ciavaglia, Emily Davis and Shane Tobe. To all of my brilliant friends and labmates that have shared this experience in some way or another, supporting and encouraging me at every step and hurdle along the way: Skye, Ashlyn, Viviana, Mangos, Kevin, Alicia, Anastasia, Jackson, and Christine. You are all champions.

I would like to thank my husband, Joel, and all of our family. You have all helped me to keep perspective and to keep laughing, continued to believe in me and shower me with endless love and support. Joel – I love you more than I could ever express. This is for you and Florence.

Canine DNA Detection:

Case 2 – Determining the presence of canine DNA in an extraction obtained from a glove

Case 3 – Determining if the canine DNA from Case 2 matches bone DNA from exhumed pet

Case 4 – Determining the presence of canine DNA in a sexual assault allegation

CHAPTER 1

Introduction to Forensic DNA Technology

Introduction to Forensic DNA Technology

1.1 Analysis Process

From crime scene to DNA report, a series of validated protocols are implemented in order to transform biological evidence into DNA information relevant to a case. Once biological evidence has been identified and collected, it is sent to a forensic laboratory where the DNA may be extracted, quantified, amplified and analysed.

The DNA extraction and quantification steps assist in determining the quantity and quality of the DNA recovered, such that subsequent amplification of specific regions of nuclear DNA using the enzymatic process PCR is successful. PCR creates millions of copies of the targeted DNA fragments. Once amplified, the DNA fragments are separated and detected using fluorescence methods and CE to determine the size of each fragment followed by data analysis using computer software. Once the resulting profile of a sample has been interpreted, it can then be compared to the DNA profiles from other evidentiary items or reference samples of individuals or suspects. Reports will contain evidential weights (commonly in the form of a likelihood ratio) for the samples under investigation; this determines the probability of obtaining the evidence given competing scenarios. These statistics are based on population frequencies of STR alleles, often obtained from online databases; derived from collections of profiles obtained from unrelated individuals. The comparison process can lead to several different outcomes: a known individual can or cannot be excluded as a possible contributor to the DNA profile obtained from the evidentiary item; the DNA typing results are inconclusive or uninterpretable; or the results from several evidentiary items are consistent or inconsistent with originating from a common source.

From start to finish, the analysis process requires large amounts of time, resources and human input that are not always available. The typical workflow shown in Figure 1.1 demonstrates that a minimum of 10 hours is required from start to finish. An increasing demand for DNA evidence and a push for fast results have created a bottleneck in the workflow at many laboratories [1]. The introduction of automated and robotic platforms designed to cope with a high throughput of samples has helped deal with capacity and backlog issues. The demand for DNA processing comes from two main areas: increased collection of DNA evidence in criminal cases, and increased collection of DNA samples from convicted or arrested individuals [2]. DNA evidence can easily be seen as a panacea by investigating authorities leading to the submission of multiple samples from a scene to the laboratory. Despite the adoption of automation in the laboratory, the problem still remains that the demand for DNA analysis is increasing faster than most labs can handle. There is also a public perception, known as the ‘CSI effect’, that DNA evidence always provides informative results and

is therefore expected for every sample. To push through the bottleneck, a balance between prioritising and pre-screening DNA casework samples for submission versus the efficiency and capacity of the laboratory to deal with the input needs to be an ongoing focus.

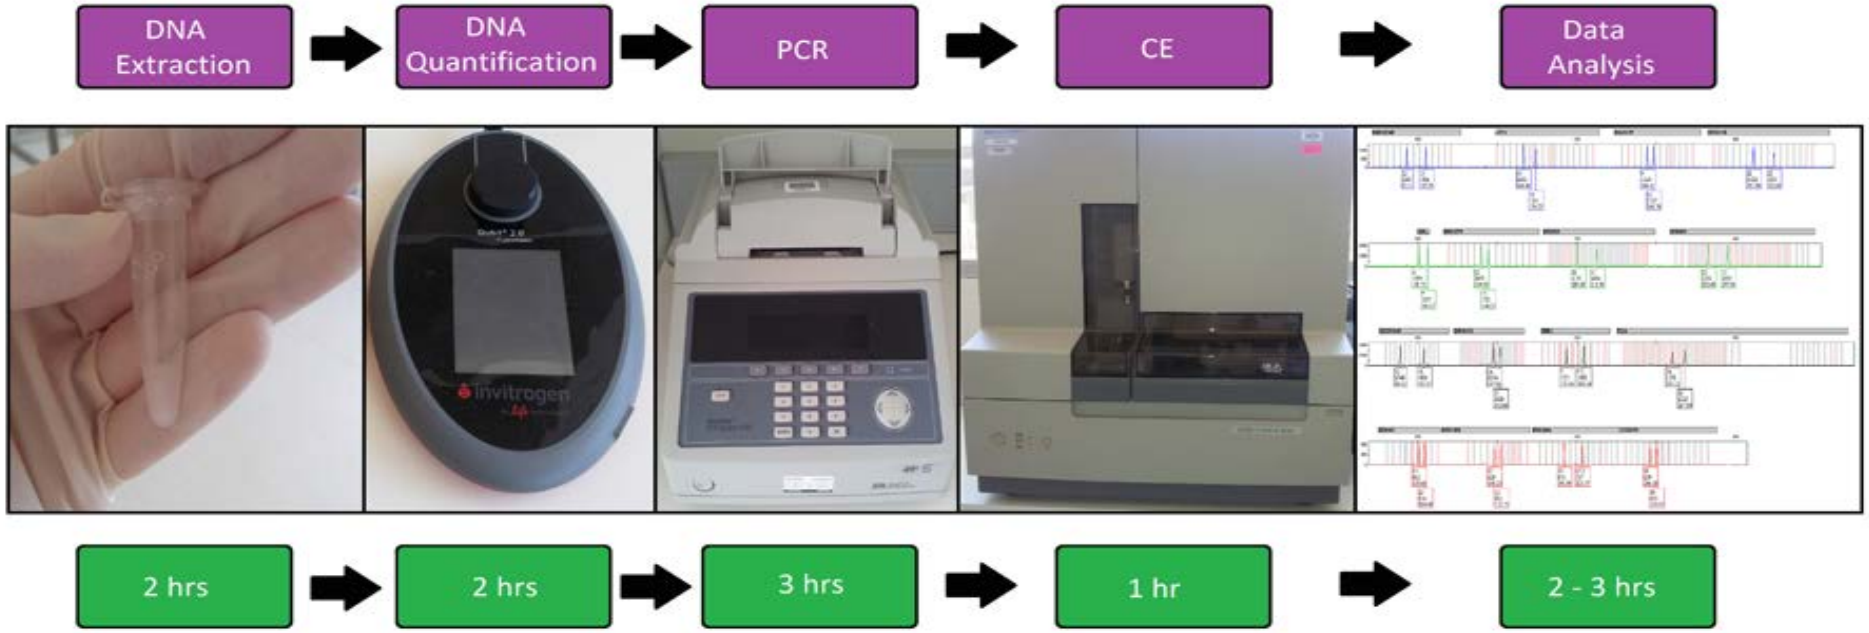

Figure 1.1 – The standard process for DNA analysis showing the time taken for each step. Typically an extraction process from blood or a buccal swab takes two hours to complete; quantification by real-time PCR takes a further two hours; amplification of STR loci a further three hours; separation on capillaries an hour per 16 samples; and finally data analysis. The total time is no less than ten hours in total. In certain circumstances, the need and advantages of obtaining DNA results quicker has lead to the development of rapid DNA instruments by biotechnology companies. The entire process can be completed in as little as 90 minutes, however the technology is considered to be in early stages and has not yet been widely adopted [3, 4].

1.1.1 Extraction Process

1.1.1.1 Importance of DNA extraction

In order to maintain optimal conditions for the downstream processes of DNA analysis, the extraction process is necessary to purify DNA from biological material and remove PCR inhibitors, such as haemoglobin, that would otherwise cause the amplification reaction to fail [5]. Multiplex PCR systems are very sensitive and rely on the correct balance of buffer constituents and reagents in order to amplify DNA successfully. The buffer is typically made up of Tris-HCl (pH 8.3), $MgCl_2$, primers, DNA polymerase, dNTPs, and DNA template at optimal concentrations; other reagents such as BSA and DMSO may also be added to help stabilise the reaction [5-10]. Inhibitors can affect PCR by interacting with the DNA, interfering with the enzyme itself, reducing the availability of cofactors or by affecting the ability of the cofactors to interact with the enzyme [11]. Depending on the type of forensic sample, specific collection techniques are implemented to avoid the unnecessary collection of inhibitors. DNA clean-up systems are marketed for this purpose, however this adds additional time to the overall process and contributes to the possibility of DNA loss and extraneous DNA contamination.

There are several methods of extraction that can be employed for minimising the transfer of inhibitors. The three most common DNA extraction techniques used in forensic laboratories, outlined in Figure 1.2, are: organic extraction, Chelex® extraction, and solid phase extraction. The choice of which extraction method to use varies greatly depending on the difficulties associated with extracting DNA from a particular substrate or sample type. The substrate type is known to affect DNA transfer and subsequently the efficiency of the DNA extraction method [12], with more difficult substrate types, such as bone, requiring further research, validation, and optimisation [10, 13-16]. The extraction method itself has also been identified as a factor of DNA yield variation [17-22], highlighting the importance for a laboratory to understand the limitations of different extraction methods. There are several studies that compare extraction method efficiency when focused on a certain substrate or sample type; this is accomplished using varying volumes of whole blood or saliva, and comparing the quantity of DNA obtained [21, 23]. These methods of comparison typically rely on the amount of DNA in whole blood or saliva to be directly proportional to its volume and does not factor in possible variance caused by the presence of cell-free DNA [24, 25]. For the most part though, a full DNA profile can be obtained from a sample typically submitted for forensic analysis; but as the demand for DNA testing increases, so does the testing of trace DNA samples. The efficiency of the extraction method for degraded or trace DNA samples needs to be high in order to avoid interpretation issues at the analysis stage, which may lead to disputes in a courtroom [19, 26].

The amount of purified DNA obtained from the DNA extraction step can vary greatly depending on the method used and the substrate that the DNA is deposited on, opening up the process to errors that could affect the overall profile quality [12]. Extractions are susceptible to exogenous DNA contamination or sample-to-sample contamination due to multiple tube changes and the extensive handling involved. This issue is amplified when dealing with samples containing minute traces of DNA, typically less than 1 ng [12, 27-29]. Multiple tube changes are often required for the removal of inhibitors via wash steps, but can also cause the loss of DNA due to tube binding, or simply by being discarded with the supernatant [24, 25]. Published studies on comparison methods and in-house validation processes have led to the common knowledge within the forensic science field that a lot of DNA can be lost to the extraction process [18, 22, 30-33]. To combat these issues and adapt to a forensic science workflow, commercial kits are evolving to include fewer steps to reduce time taken, lower contamination risk and incorporate low-DNA binding plastic-ware, with laboratories also implementing automated extraction methods to help reduce the risk of contamination and to better cope with the increased work demand [34-40].

FTA™ paper (Whatman) is a medium for DNA storage, which can be extracted by using a number of methods. It is utilised by biotechnology companies, with reference kits manufactured specifically for use with direct PCR and FTA™ punches, such as GlobalFiler® Express, to reduce the steps involved in the analysis process and decrease the overall time of analysis [41-43]. The paper is cellulose-based and contains chemicals to protect the DNA from degradation, developed by Leigh Burgoyne at Flinders University in Australia [44]. This enables DNA to be stored at room temperature for several years. The DNA in body fluids such as blood or saliva can be stored on the paper by pipetting or swab transferring to the circular area outlined on the paper. The cells begin to lyse once transferred to the paper and DNA is fixed within the matrix. Once dry, a small section of paper is punched out and transferred to a tube for extraction. Solvents, such as iso-propanol, can be used to remove haem and other inhibitors present on the paper. After cleaning, the paper punch is transferred directly to the PCR tube for amplification.

The FTA procedure provides long term stable storage at room temperature with consistent results [45]. Although the process may be automated for faster results and multi-sample processing [46, 47], automation using FTA card has not gained traction due to the effects of static electricity. The small, dry paper discs have a tendency to ‘jump’ from their tubes or wells, possibly into other sample tubes causing contamination, or lost to other surfaces resulting in loss of information [48]. FTA™ has remained a popular medium for the storage of samples due to its preservation

capabilities, particular in the collection of crime scene evidence or storage of reference DNA that may need further sampling [49-52].

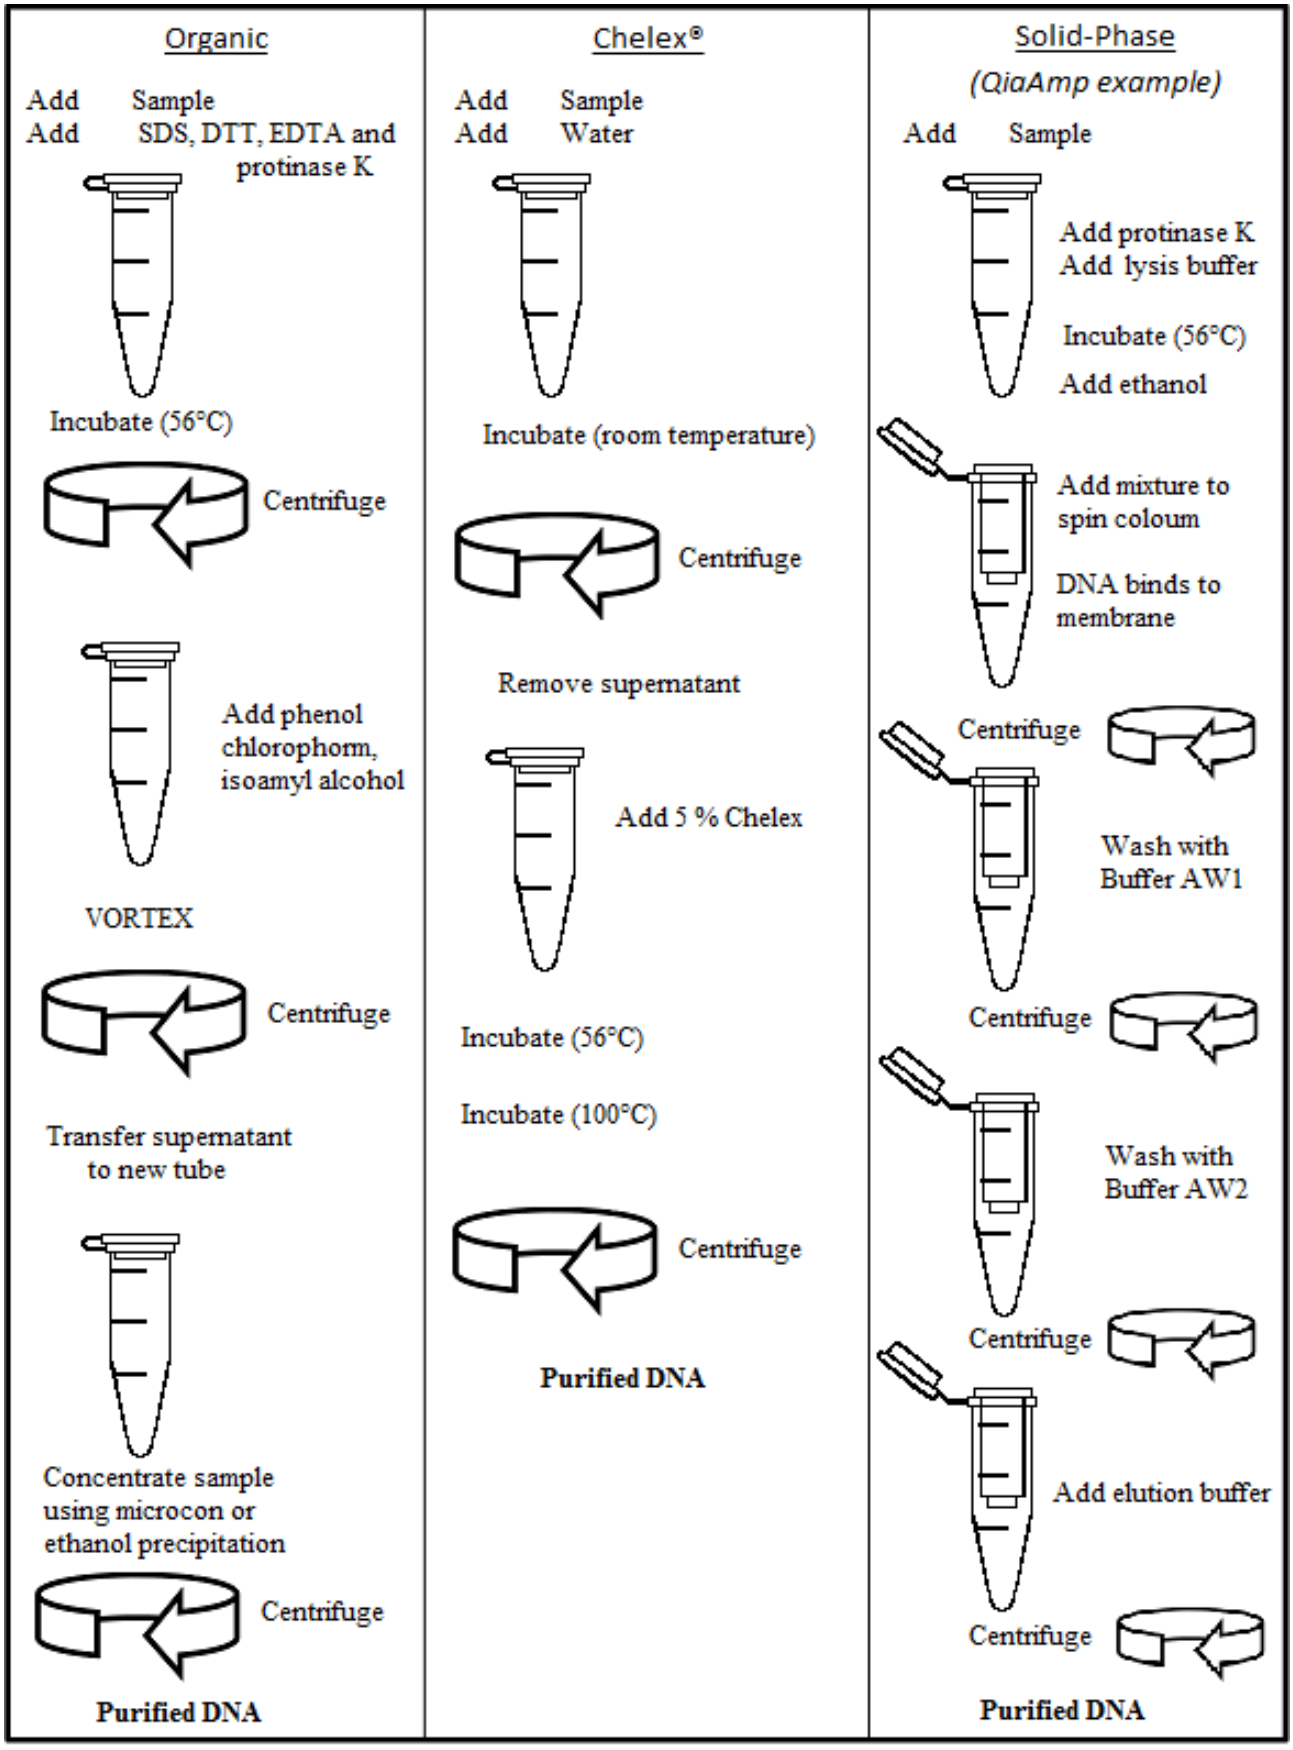

Figure 1.2 – Overview of the three most common extraction techniques.

1.1.1.2 Organic or phenol-chloroform extraction

Organic extraction is ideal for high recovery of DNA from samples, however the process is lengthy and involves the use of hazardous chemicals [10, 13]. Initially, SDS and proteinase K are added to break open the cell membrane, nuclear envelope and the proteins that encase the DNA molecules such as the histones. This is followed by the addition of a phenol/chloroform mixture to separate these proteins from the DNA molecules. This is based on the solubility of proteins into phenol under these conditions while the DNA remains soluble in the extraction buffer. Centrifugation then separates the aqueous phase containing double-stranded DNA from the dense organic phase containing cellular and protein debris, allowing for collection and transference of the DNA to a separate tube. The protocol is often repeated several times to increase the concentration and purity of the DNA yielded. Although the process is difficult to automate and requires numerous tube changes, the process does provide relatively pure DNA, depending on how it is initially collected.

1.1.1.3 Chelating resin – Chelex®

Chelex® 100 (Bio-Rad Laboratories) is more rapid than organic extraction as it involves fewer steps, and therefore fewer chances for exogenous contamination. It is also safer, simpler and overall reduces laboratory costs. It produces single stranded DNA and therefore is only suitable for PCR related analysis. A chelating-resin suspension is added directly to the sample, typically creating a 5% Chelex® suspension. It is composed of styrene divinylbenzene copolymers containing paired iminodiacetate ions that act as chelating groups in binding polyvalent metal ions such as magnesium [48, 53, 54]. This attracts and binds magnesium (Mg^{2+}), calcium (Ca^{2+}) and iron (Fe^{2+}) in the sample so that the molecules cannot activate nucleases that destroy DNA (Mg^{2+} is the DNAase co-factor and hence an inhibitor if not removed). This protects the DNA molecules within the sample. Once Chelex® resin has been added to the sample, it is boiled for several minutes to break open the cell membranes to release the single-stranded DNA. Spinning the sample in a centrifuge will move all Chelex® resin, cellular and protein debris to the bottom of the tube allowing for the supernatant containing the DNA to be removed easily. Chelex®, however, tends to be more sensitive to inhibition from certain sample types as only 2^+ ions are removed, hence other cell content that is able to co-extract with the DNA remains. This therefore affects the downstream processes and STR results, showing it to perform particularly poorly with degraded DNA samples [22, 32]. There is no purification step in this method to remove inhibitors or contaminants; wash steps may be implemented to assist in removing some inhibitors such as haem from blood, but additional tube changes may cause loss of DNA. Chelex® is a predominantly manual method, but can be modified and partially automated to assist with processing time and reduction of contamination risks [55].

1.1.1.4 Solid-phase silica

Solid-phase extraction is available in many formats of commercially manufactured kits. The process involves separating compounds, either dissolved or suspended in liquid, based on their physical or chemical properties. They are often the preferred method of extraction due to ease of use, high DNA yields, ability to be automated, removal of inhibitors and they do not use hazardous chemicals [23, 40, 56, 57]. Two companies Qiagen Inc. and Promega Corporation produce the most commonly used solid-phase extraction kits in forensic science, utilising spin columns, silica bead and magnetic bead technology.

The Qiagen QIAamp® spin columns use small glass beads to selectively absorb nucleic acids. In the presence of high concentrations of chaotropic salt, hydrogen-bonding networks in the water will be disrupted, causing denatured proteins and nucleic acids to be more thermodynamically stable than their non-denatured form [48, 58-61]. Multiple buffer washes contribute to the removal of DNA degrading cations, such as Mg^{2+}, as well as other impurities and inhibitors, leaving approximately 95 % of the DNA to be bound by charge to the silica membrane in the column when pH is less than 7.5 [48]. To release the DNA from the silica beads in the membrane, an alkaline elution buffer is used to reverse the binding.

The DNA IQ™ System (Promega) is a semi-solid-phase extraction method, employing the same wash, DNA binding and elution steps as Qiagen kits, but use silica-coated magnetic resin instead of beads [40, 62]. This approach allows the extraction to be performed in a single tube, reducing DNA loss, as DNA can bind to the surface of tubes each time a new one is used. Like the Qiagen method, DNA will bind reversibly (to the magnetic resin) when the pH is less than 7.5. A magnet is used to separate the resin from solution by drawing the resin to the side of the tube allowing for the easy removal of the solution containing impurities and cell debris. The resin is washed repeatedly to ensure the efficient removal of inhibitors. To release the DNA from the resin it is heated for several minutes. This one-tube-method is a major benefit as it is fast and simple, making it ideal for automation within forensic laboratories, enabling fast processing of large sample numbers. Although solid-phase silica extraction methods produce higher purity DNA extracts than Chelex® extraction, the commercial kits are expensive and not very efficient at binding DNA, resulting in a high loss of template DNA [23, 30].

1.1.2 Quantification of DNA

1.1.2.1 Why quantify?

DNA quantification determines how much DNA is present in an extract. This information is valuable and necessary in order to optimise downstream processes such as PCR and profile analysis. For example, commercially produced human DNA profiling kits are optimised for initial DNA starting templates typically between 0.5 – 2.5 ng of DNA at the PCR stage. The original profiling kits such as SGM® and Profiler® required 2 ng of input DNA, this reduced to 1 ng for SGM Plus® and now to 0.5 ng for newer kits as buffer constituents and polymerases become more robust, thus increasing the sensitivity. Info Box 1.1 shows how human genomic DNA quantities are calculated. Quantification allows for the optimal amount of DNA to be used; when too little or too much DNA is added to sensitive reactions, adverse outcomes may arise. Too much DNA can result in incomplete adenylation (split-peaks), off-scale peaks, and locus-locus imbalance [48] as well as excessive background noise created by too much DNA fluorescence (detected during capillary electrophoresis) making profile analysis very difficult. Too little DNA can also cause locus-locus imbalance, as well as stochastic amplification where heterozygous alleles amplify unbalanced or not at all, resulting in 'drop-out' of an allele [63-66]. Drop-out typically occurs with larger DNA fragments and can cause heterozygous loci to appear as homozygous. To reduce stochastic events, several methods have been developed for DNA quantification, with a focus on human-specific methods in forensic science [67]. Human-specific methods are important for forensic science applications, as mentioned previously, the initial starting template for optimised reactions in human identification is quite narrow. Each method for DNA quantification continues to evolve to meet the needs of the forensic laboratory: simplicity, speed, cost, accuracy, automation and adaptability. Comparison studies of quantification methods have also highlighted the need for international [68] standard methods and standard reference materials to minimise variation between laboratories, and identify the best protocols for each sample type [69, 70].

Calculation of DNA quantities in human genomic DNA:

1 bp = **618 g/mol**
A = 313 g/mol; T = 304 g/mol; A-T base pairs = 617 g/mol
G = 329 g/mol; C = 289 g/mol; G-C base pairs = 618 g/mol

1 genome copy = **~3 x 10^9 bp** = 23 chromosomes (one member of each pair)

1 mole = **6.02 x 10^{23} molecules**

1 genome copy = (~ 3 x 10^9 bp) x (618 g/mol/bp) = 1.85 x 10^{12} g/mol
= (1.85 x 10^{12} g/mol) x (1 mole/6.02 x 10^{23} molecules)
= 3.08 x 10^{-12} g = **3.08 pg** in a haploid cell

∴ a human diploid cell, containing two copies of each chromosome will contain **~ 6 pg** of genomic DNA

Human DNA kits optimised for ~ 1 ng of genomic DNA (1000 pg)
= **~333 copies** of each locus
(2 per 167 diploid cells)

Info. Box 1.1 Important values for calculating DNA quantities, adapted from Butler [48].

1.1.2.2 Slot Blot

Slot blot utilises a 40 base pair (bp) probe that binds to locus D17Z1 in humans and higher primates, showing a high degree of species specificity [67, 71]. Once extracted and denatured, the single-stranded DNA is bound to a positively charged nylon membrane. The probe is then applied and hybridises with the DNA. The hybridised complex can be detected using chemiluminescent or colorimetric signal intensities where the unknown samples are compared to a set of standards of known concentrations. The amount of DNA is estimated based on these comparisons. Chemiluminescence is more sensitive as the reaction causes the release of protons that are captured on a CCD camera and can detect down to 10-40 pg of DNA [72]. The commercially produced kit QuantiBlot® Human DNA, developed by Applied Biosystems, was short lived due to the worldwide adoption of more sensitive, faster and efficient methods, and was discontinued in 2007. A large amount of extracted DNA may be lost due to the set-up of this method, as the slot blot plate apparatus requires a minimum working volume. This is not ideal for forensic science purposes where limited extracted DNA is available, or if the extracted DNA is required for further independent testing. The method of measurement is also highly subjective as the intensity of spots for unknown samples compared to the calibration standards are estimated, with unknown samples often falling between two calibration spots. Negative controls often gave full DNA profiles, as the apparatus used is more open to cross-contamination than other methods.

1.1.2.3 Spectrophotometry & Fluorometry

UV spectrophotometry can quantify DNA by measuring the absorbance of a sample at 260 nm without the use of standard curves, detecting concentrations down to 2.5 ng/μL. Although this method is relatively fast, the limit of detection is not sensitive enough for most forensic purposes. Fluorescence tagging methods have become more popular in forensic science as the use of intercalating dyes is more sensitive than UV spectrophotometry. Intercalating dyes will bind to DNA and then fluoresce when excited. The measured fluorescence is compared to a standard curve and can detect DNA concentrations as low as 100 pg/μL. Intercalating dyes and UV spectrophotometry methods quantify the total DNA in a sample and are not human specific. The sensitivity and effectiveness of the dyes can also vary greatly depending on the dye used [73, 74]. For example ethidium bromide and PicoGreen both selectively bind to dsDNA, however PicoGreen is safer, more sensitive and has a substantially higher fluorescence than ethidium bromide [74]. The development of the Qubit® Fluorometer (Life Technologies), seen in Figure 1.3, has enabled the fast and accurate measurement of DNA, RNA and protein in the laboratory. The benefits of this small bench-top device include a small sample input, as low as 1 μL, with a total set-up and run

time being as fast as just a few minutes. The disadvantage for forensic samples is that it is not human-specific as all DNA is detected.

Figure 1.3 – A bench top UV spectrophotometer (left) and a newer style Qubit® 2.0 Fluorometer (right).

1.1.2.4 Real-time PCR

Real-time PCR or quantitative PCR (qPCR) is a fluorogenic method that measures the total amount of amplifiable genomic DNA. There are two variations of this technique used in forensic science. The first is the measurement of *Taq* polymerase activity using an intercalating fluorescent dye, such as SYBR® Green or ethidium bromide, to bind to double-stranded DNA [75]. The second is to measure the 5-nuclease activity of the *Taq* polymerase, such as TaqMan®, to cleave a target-specific fluorescent probe [76]. In both instances, the fluorescence is measured as it accumulates with each PCR cycle and compared against a standard curve with known concentrations (Figure 1.4). Human-specific regions can also be targeted during this PCR process, most commonly multi-copy Alu sequences, which appears up to one million times throughout the human genome [77, 78]. Companies such as Applied Biosystems and Promega have developed numerous commercial kits providing efficient, accurate and species-specific quantification [77]. This method is typically the preferred method for forensic samples as it can be automated allowing for high throughput

processing, adapted to simultaneously perform different qualitative analysis such as sex determination, mtDNA degradation, and cross species quantitation, detects low levels of DNA, and is human-specific [79-81].

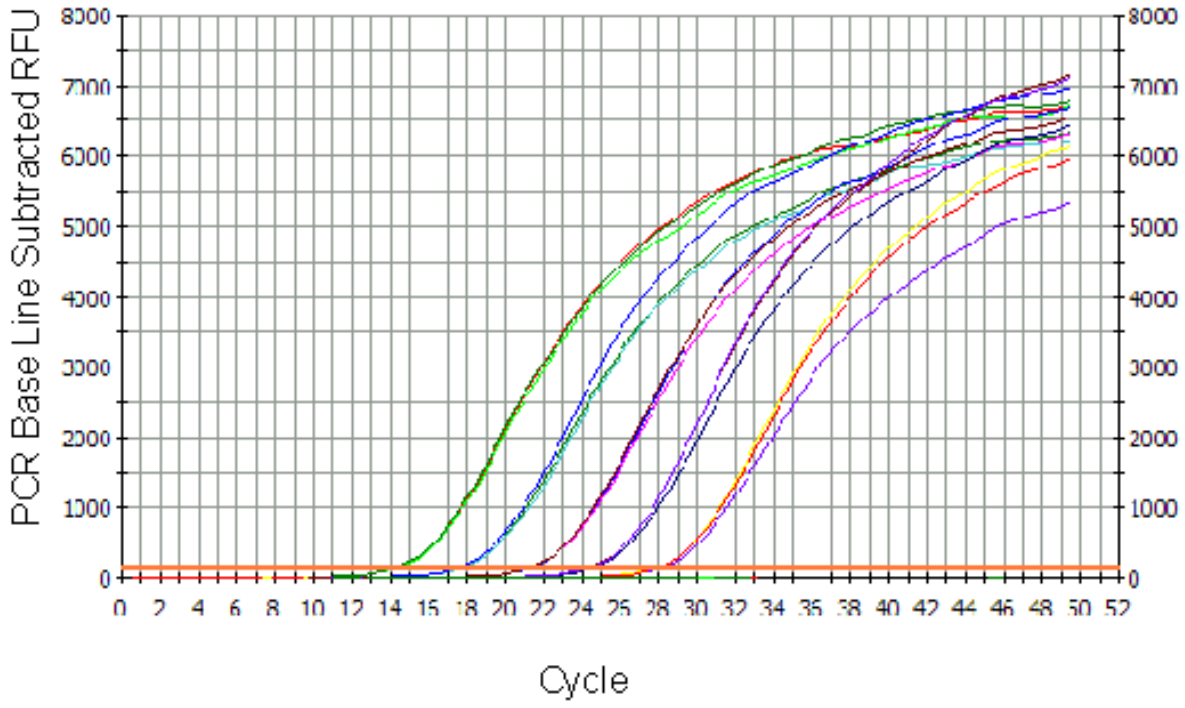

Figure 1.4 – Amplification curves obtained from serial dilutions of target DNA using real-time PCR. *Figure source: http://www.etsu.edu/com/mbcf/Services/pictures/pcr1.gif*

1.1.3 Capillary Electrophoresis

The final experimental step of the analysis process is the separation of the PCR products to obtain a DNA profile. Human identification kits target multiple STR fragments that need to be separated from each other to a one base pair resolution, such as TH01 alleles 9.3 and 10, so that individual alleles can be distinguished from one another. To ensure reproducibility between laboratories worldwide, advanced genetic analysers that utilise CE methods are used, offering high resolution and accuracy [82-84].

The capillaries are made of a thin fused silica (glass), with an inner diameter ranging from 50 – 100 μm and a length of 25 – 75 cm, capable of holding a sieving polymer. The properties of the capillaries allow for greater heat dispersion thus enabling higher electric fields, resulting in faster separation [85]. The polymer contains a high concentration of urea to maintain an environment within the capillary that will keep DNA molecules denatured, allowing the fragments to move consistently through the polymer matrix, as the mobility of the DNA fragments can be affected by its conformation [86, 87]. Prior to injection, PCR samples are diluted in deionized formamide with an internal size standard, and heated to 95 °C to ensure the DNA molecules are single stranded. Pores within the polymer matrix aid in the size-based separation of the PCR fragments; smaller fragments can move more freely between the pores and elute faster than the larger fragments that become entangled within the matrix [88, 89]. The PCR fragments, comprising of DNA, are pulled through the capillaries and polymer matrix using an electric current. As the phosphate groups on the DNA backbone are negatively charged, the DNA fragments can be separated over the length of the capillary using an electric current flowing from the cathode to the positively charged anode [88]. A detection window is located on the capillary just prior to the anode, where individual fluorescently labelled DNA fragments are detected by laser-induced fluorescence. Fluorescent dyes used in STR DNA labelling emit light ranging from 400 – 600 nm, in the visible region of the spectrum, allowing them to be distinguished from one another based on their specific emission wavelength. The maximum fluorescence of each dye passes through a diffraction grating and is captured by a CCD camera [48]. Raw data of the measured fluorescence signal are obtained and compared to spectral matrix calibrations for each dye signal. GeneMapper® analysis software automatically analyses the data, revealing a DNA chromatogram.

Major benefits of CE methods over slab gel methods includes the overall reduced time in the set-up of the instrument, sample preparation and separation, all of which can now be fully automated [90]. Reproducibility, resolution, cross-contamination and sample consumption are also greatly improved in the CE system.

1.1.3.1 Genetic analysers

The most commonly used CE systems in forensic science are manufactured by Applied Biosystems/ Life Technologies. The first system developed, the ABI Prism® 310 Genetic Analyser, consisted of a single capillary able to process one sample at a time. To assist with the high workflow of forensic samples, CE systems have evolved to include more capillaries per array. The ABI Prism® 3100-Avant and 3130 house a 4 capillary array, increasing to 8 capillaries in the 3500, and further increasing to 16 capillaries per array in the 3100 and 3130*xl* series. The 16 capillary array systems are the most commonly used due to the speed of processing samples (approximately 45 minutes), low contamination issues, and greatest precision and sizing accuracy when compared to other CE systems [91].

Human DNA identifying kits continue to evolve by increasing the number of loci targeted. It is important that the range of loci does not overlap in size with others; using multiple dyes in the multiplex assures there is no overlap (Figure 1.5). CE systems typically consist of 4 or 5-dye technology, where one dye is reserved as a size standard, and the remaining dyes are used to label the STR fragments. GlobalFiler® is the latest kit by Life Technologies, incorporating 6-dye, 24-locus technology offering reduced amplification time with the highest discrimination power available. With this increase in dyes, a new CE system has been developed, the 3500 Genetic Analyser, to accommodate the 6-dye technology.

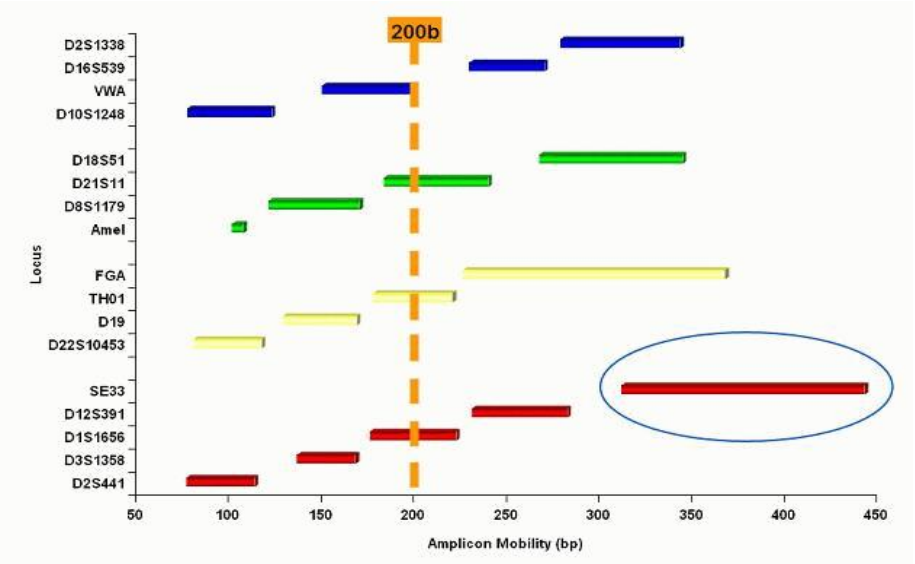

Figure 1.5 – Loci and dye arrangement for the AmpF*l*STR® NGM SElect™ (Life Technologies) human identification STR kit. Four dyes (blue, green, yellow, and red) are attached to primers for DNA STR amplification; the fifth dye (orange) is used as an internal sizing standard during CE. Circled locus indicates the additional locus between the NGM™ kit and NGM SElect™ kit.

As the demand for DNA sampling and rapid analysis continues to increase, the CE systems continue to evolve. Portable CE units developed on microchips, known as microfluidic devices, are being manufactured that can be used on-site at an investigation [92-95]. These units process the sample from DNA extraction through to STR or SNP analysis, giving results in as little as 90 minutes, thus speeding up the analysis process dramatically [96, 97]. These instruments are generally considered to be in the early stages of development, and have not been widely adopted yet.

1.1.3.2 RFU measurements

RFU are the recorded electric signals detected using software when the fluorophore attached to the DNA fragment is excited during CE. The fluorophore will absorb the laser energy and emit light at a particular wavelength. The spectral overlap of the dye sets used, as observed in Figure 1.5, is accounted for using statistical software and a preinstalled mathematical matrix that subtracts the contribution of all other dyes within a single dye measurement [48]. This ensures the results observed are from an individual dye colour and not a mixture of the spectral overlap. The stronger the signal, the brighter the fluorescence of that dye will be and a greater RFU value will be recorded. The RFU measurement is not an SI unit, but developed by ABI for use with their systems.

RFU thresholds for forensic DNA analysis are essential to maximise the detection of alleles, and to maintain universal standards for analysis methods. However, these standards may vary between each lab from 25 – 200 RFU, depending on whether the peaks are heterozygous or homozygous, and the method of threshold determination used [98]. Many laboratories are moving to continuous models for DNA interpretation and use +3 SD above the baseline to determine the stochastic RFU threshold [99-102]. The thresholds are most commonly determined by analysing the signal-to-noise ratio of blank signals after processing. The baseline noise begins to increase substantially with higher levels of DNA, causing a bleed through of the overlapping spectral colours, known as ‘pull-up’ [48, 98]. Excessive pull-up may also cause peaks to present themselves as off-ladder. Each kit identifies an optimal amount of template DNA in order to avoid these issues.

1.1.4 Profile Analysis

Once the data have been collected and processed by the relevant software, the resulting DNA profile is ready for analysis. The analysis can be affected by numerous factors, including the analysis strategy used, the nature of the DNA profile (mixed or single source), bias, and the experience of the DNA analyst [103]. Software such as FaSTR DNA offers automation of the DNA profile analysis step to increase consistency and save analysis time [104]. Statistical and continuous models, including mixture interpretation software, have been developed as a way to unify the analysis process as much as possible, and reduce variation [98, 100, 102, 105]. The factors affecting analysis therefore affect the resulting match probabilities and likelihood ratios. This leads to a concern of possibly over or understating the evidential impact of a match, particularly where kinship or mixed profiles are involved [106], having significant consequences within a courtroom [103, 107-109]. Due to the impact of different DNA interpretation methods there has been a push within the forensic science community for standardisation, with a shift from threshold-based interpretation towards continuous interpretation strategies [110].

1.1.4.1 Standards

The quality assurance standards for all types of forensic DNA analysis in the USA are governed by SWGDAM. SWGDAM are a group of forensic scientists that represent international, federal, state and local forensic DNA laboratories. They provide guidelines and documents for the direction and guidance within the community for forensic casework analysis, covering areas of nuclear DNA, mitochondrial DNA, population genetics, statistics, STRs and Y-STRs, as well as the identification and application of threshold for allele detection and interpretation, appropriate statistical approaches to interpretation of autosomal STRs and mixture interpretation. The group meet twice a year to review standard operating procedures, recommend research to be conducted or methods to be validated, and encourage laboratories to review their procedures based on the findings. In addition, any laboratory that analyses DNA samples for forensic casework purposes is required by the Quality Assurance Standards for Forensic DNA Testing Laboratories to establish and follow documented procedures for the interpretation of DNA typing results and reporting [111, 112]. The procedures are based upon validated studies, scientific literature and experience. Similarly to SWGDAM, commissions presented by the ISFG are followed by many laboratories outside of the USA [113].

The guidelines continue to evolve as new technologies emerge; however until recently (October 2014), the guidelines have not extensively addressed the validation, standardisation and interpretation of analytical results from enhanced low template DNA techniques [114]. This is

because the technology is still relatively new, with varying methods, making the overall interpretation of DNA typing results for human identification purposes particularly difficult when low-level DNA samples are involved, thus requiring professional judgement and expertise [66, 105, 115-120].

1.1.4.2 Contamination

SWGDAM and the ISFG also provide guidelines for precautions against contamination, as many studies have shown contamination to arise from various stages within the analysis process [111, 121-125]. For the most part, contamination can be avoided or greatly reduced by following the appropriate protocols and procedures and can be more easily identified with the aid of staff elimination databases, isolated laboratory sampling areas, negative controls and regular testing of lab ware and supplies [48, 126, 127]. As mentioned previously, trace DNA samples pose their own set of difficulties with interpretation and analysis. As the technology implemented in trace DNA work involves more sensitive testing, contamination is more likely to be seen and possibly go undetected, and thus compound the difficulties of the analysis process [127-129]. The impact of contamination has obvious serious ramifications when it comes to criminal investigations and prosecution [125, 127].

1.2 DNA Technology

The value of DNA evidence in a forensic investigation has increased momentously since DNA fingerprinting was first described [130], a major scientific breakthrough that allows a unique DNA profile of an individual to be recorded. The continued collaboration around the world towards DNA databases has enabled strong statistical weighting to be applied when comparing DNA samples, often making DNA the strongest link of evidence in a criminal investigation. Each one of our cells contains DNA within the nucleus and DNA within the mitochondria, except for mature red blood cells that lack a nuclear component. Investigations involving biological cellular material will utilise a set of validated protocols and steps to retrieve and analyse the important DNA information within. This DNA may be present in body fluids such as saliva, blood (white blood cells), or semen, or may be retrieved from other sources such as hair, fingernails, teeth, tissue or fingerprints.

1.2.1 Short Tandem Repeat Typing

STR markers or microsatellites are repeated DNA sequences found on a genome, typically consisting of a two – six bp motif. In forensic science, STR technology evaluates specific locations (loci) on the nuclear DNA. These areas are variable in nature (polymorphic), increasing the discrimination value between profiles of unrelated individuals [64, 65, 131-134]. The first basic multiplex, 'the quad', was developed in the UK by the Forensic Science Service (FSS) in 1994, followed quickly by the 'six-plex' Second Generation Multiplex system in 1995 and was used to create the world's first national database [135]. By 1997, the FBI has established a set of 13 core STR loci to serve as the standard for CODIS (most of which, if not all, are incorporated into currently used commercial human identification kits) [136, 137]. The aim of the core set is to ensure uniform standards and DNA database systems across the forensic science community, as well as sharing valuable forensic information.

STR human identification kits are capable of generating results from very small amounts of DNA across an increasing number of loci. The loci fragment lengths range from 100 – 450 bps. When DNA is exposed to nature's elements, arising in certain forensic situations such as DVI, degradation can occur due to bacterial, biochemical or oxidative processes [138, 139]. When degraded DNA is amplified, it is common to see dropout of the larger fragments as well as peak-imbalance [140, 141]. This is generally caused by the presence of PCR inhibitors, and DNA fragmentation that has occurred prior to amplification making full amplification incredibly difficult. To combat this issue, amplification primers are placed as close as possible to the core STR repeat to create 'mini-STR' systems that amplify smaller PCR fragments ranging from 50 – 250 bp in length [138, 142-145]. Many of the mini-STRs identified are linked to the CODIS system, enabling use of the same

databases [138]. However, a number of studies have also shown the successful analysis of degraded DNA using mini-STRs unlinked from the CODIS markers [142, 144, 146], enabling further assistance in the forensic analysis of difficult DNA samples. Human STR identification systems continue to evolve to include a greater number of loci, as well as smaller and more stable loci in order to adapt to the difficulties faced in forensic investigations, such as GlobalFiler® incorporating ten mini-STRs (Figure 1.6).

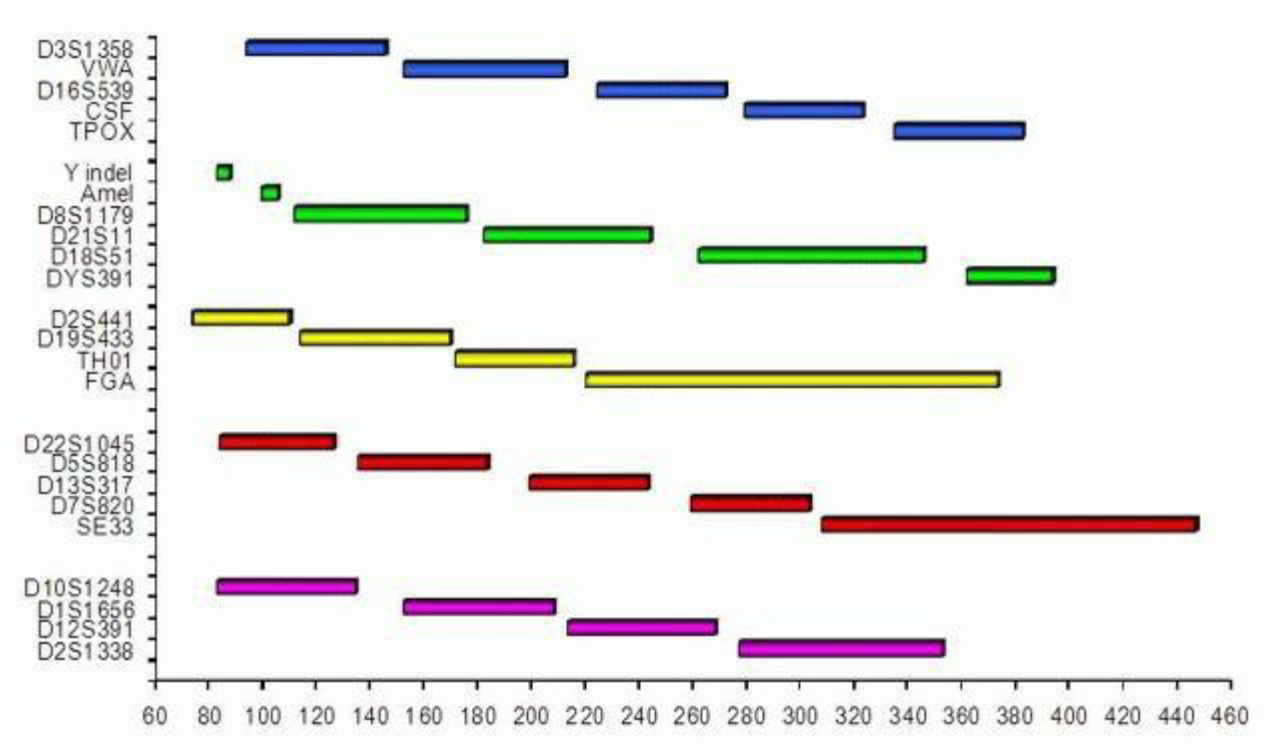

Figure 1.6 – Loci and dye arrangement for the GlobalFiler® (Life Technologies) human identification STR kit. The kit is the first to incorporate 6-Dye technology as well as ten mini-STR loci to reduce the amplification time, maximise results from degraded samples, and increase discrimination power.

1.2.2 Y-STRs

STR markers have also been identified on the Y-chromosome for forensic application, known as Y-STR markers. Y-STRs are lineage markers that are passed unchanged (except for mutation events) through the paternal line. As lineage markers remained unchanged through each generation, they are not as effective in differentiating between two individuals. However, Y-STR markers have proven to be a valuable tool in routine forensic investigations for various applications [147, 148]. Studies involving population lineage and human migration have enabled researchers to differentiate between male individuals of different paternal lineages [149-152]. As Y-STR markers target the male DNA component only of sample, they can be applied to forensic cases such as: deficiency paternity testing [153, 154]; sexual assaults where the female DNA component of a mixed

biological sample greatly outweighs the male DNA component or where there may be multiple male contributors [155-157]; and missing person or DVI investigations [148, 158]. The number of Y-STR markers used in multiplex systems has continued to increase [155, 159-161] but they are still unable to distinguish between related male individuals from the same paternal line. Due to this demand, Y-STR technology has progressed into the research of rapidly mutating Y-STRs (RM Y-STRs) to enable related individuals to be distinguished from each other [162-167].

1.2.3 Mitochondrial DNA

mtDNA is also a lineage marker that is passed unchanged each generation, through the maternal line. Autosomal STR analysis types the two copies (one paternal and one maternal) of linear nuclear DNA found in each cell, whereas mtDNA analysis types the 100 – 10,000 copies of circular DNA found in the mitochondria of each cell. The circular nature and number of copies of mtDNA means it is robust in nature, lacks recombination and is more resistant to complete sample degradation, making sequence analysis of the mtDNA hypervariable regions ideal where samples are so badly degraded that nuclear STR analysis is not possible [168-173].

Similarly to Y-STRs, the mode of inheritance means mtDNA analysis is less discriminating than nuclear STR analysis for identification purposes. However, this type of analysis still offers great information via inclusion or exclusion of individuals in forensic investigations, such as DVI scenarios, missing persons, and identifying human remains from highly degraded DNA samples such as hair, bone and teeth [174-178].

Mitochondrial analysis has several areas of limitations and important issues to consider when evaluating the results, such as: nomenclature inconsistences and the subsequent effect on reference population databases [179-181]; heteroplasmy [182-185]; paternal leakage and recombination [186-189]; and interpretation [190-192]. mtDNA testing is also a time-consuming process, more labour intensive than STR typing, not as routine or as automated in the forensic analysis process. It is recommended that laboratories undertaking mtDNA testing should have dedicated spaces, instruments, chemistry and lab wear, only tolerate low levels of contamination and be involved in regular proficiency testing programs [191]. For these reasons as well as cost, time management and resources, not all laboratories may be equipped to deal with mtDNA analysis.

1.2.4 Single Nucleotide Polymorphisms

Forensic DNA scientists often use additional markers, such as SNPs, as the need arises to obtain further information about a particular sample [193, 194]. SNP fragment sizes are similar to mini-STRs, often smaller, and are also ideal for the analysis of highly degraded DNA samples [195].

However, a SNP locus possesses only two possible alleles and therefore SNP panels require a much higher number of markers (40 – 60) to deliver a similar discriminating power of commonly used STR multiplex kits (13 – 16 loci) [193, 196, 197]. Studies are incorporating more and more SNP loci within a multiplex system, even amplifying autosomal and Y-chromosome makers together, to offer a high discriminating power to difficult forensic samples [152, 198-202]. SNPs have the added benefit of providing inference of the likely physical appearance of individuals such as hair and eye colour, as well as ancestry [194, 203-206], thus providing further means to include or exclude individuals from an investigation. As SNPs are mostly biallelic, they can be easily genotyped using the SNaPshot® Multiplex Kit (Life Technologies).

1.2.5 Low Copy Number & trace evidence

The term 'trace DNA' has many meanings and can be defined as the amount of DNA present, the quality of DNA present, DNA detected by low copy number or low template PCR, DNA that cannot be attributed to an identifiable body fluid, or the DNA transfer to surfaces of sloughed epidermal skin cells through sweat or abrasion [27, 29, 207]. Trace DNA evidence is therefore very wide-ranging and encompasses all samples that fall below recommended thresholds at any stage of the analysis process [27]. As previously stated, *Info Box 1.1*, the recommended DNA template for human identification kits is between 0.5 – 1 ng or ~ 83 – 167 diploid cells, as 1 cell contains 6 pg of DNA.

DNA is present within cellular material, but can also be found outside of the cell when cellular membranes begin to break down [208]; this is known as extracellular or cell-free DNA. Cell-free DNA can also be referred to as trace DNA as it is generally considered to be present in lower masses than cellular DNA. Cell-free DNA can be found in blood, saliva, semen and urine [25, 209, 210] as well as tested forensic samples of vomit, faeces, sweat, and buccal cells [25]. DNA can be found on a range of handled objects such as cigarette butts, clothing, nail cleaners, toothbrushes, and door handles through direct or indirect transfer, with studies showing that only minimal contact is required for skin cells and debris to be transferred to items for successful DNA results to be obtained [31, 211-214].

It has been suggested that cell-free DNA contained in sweat may contribute to the DNA profiles obtained from touched or handled items [18, 215]. This was further confirmed in a separate study where cell-free DNA was detected in the sweat of 80 % of individuals analysed [24]. In a more recent study [25], the suggestion that a substantial proportion of cell-free DNA may be lost to the extraction method, discarding potentially important forensic information, was investigated further.

This study compared the DNA profiles from the cell pellet and the concentrated supernatant, from the extraction process, and found that not all alleles present in one sample were found in the other or *vice versa* [25]. Thus, indicating that DNA information can be lost if the supernatant is discarded during extraction.

As STR PCR DNA typing technology continues to become more sensitive due to improved extraction processes, enhanced buffer systems, and greater DNA collection techniques, caution needs to be demonstrated when handling exhibits and interpreting results from trace DNA evidence, as only minimal contact can cause the transference of DNA between objects [211]. Substantial DNA transfer between individual and item (primary transfer) occurs during the initial contact [211], highlighting the importance of proper care when processing evidence and the risk of external contamination. Secondary transfer and contamination of DNA has shown to be low in several studies, indicating that although possible it is not likely to occur if proper care is taken when processing evidence [26, 29, 66, 213]. The number of factors that affect the presence or transfer of trace DNA and the ability to successfully obtain profiles from it are unknown but can include: duration of contact, the substrate surface, environmental conditions, time since depository, pressure and friction of contact, moisture, and the variation of analysis methods [26, 124, 207, 212, 216]. It has also been suggested that the success rate of DNA profiling is dependent on not only the characteristics of the DNA contributor (recently washed hands or dominant hand used), but also the activities performed by them prior to touching an item [213].

As the science of DNA developed in the late 1990s, a new analysis and interpretation of low template DNA was developed by the UK FSS, called LCN. To combat the low success rate of trace DNA evidence the PCR amplification was increased from 28 to 34 cycles [66], and is the standard for LCN PCR. LCN became a trademarked process marketed to police forces in the UK. *Info. Box 1.2* identifies important cases where LCN was implemented, with *Info. Box 1.3* explaining how new and novel methodologies is received in a court of law under the Daubert standard (applicable in the USA only). As LCN is able to detect lower thresholds of DNA, there is a real concern of incidental DNA being detected and secondary transfer therefore becomes more likely. This issue is outlined in Figure 1.7, and discussed further in *Info. Box 1.2, Reed & Reed v. R* [217]. An extensive review of LCN analysis has found the process to be a validated method, whilst also identifying advantages and limitations associated with the method and recommendations for laboratories wanting to implement the technique [218].

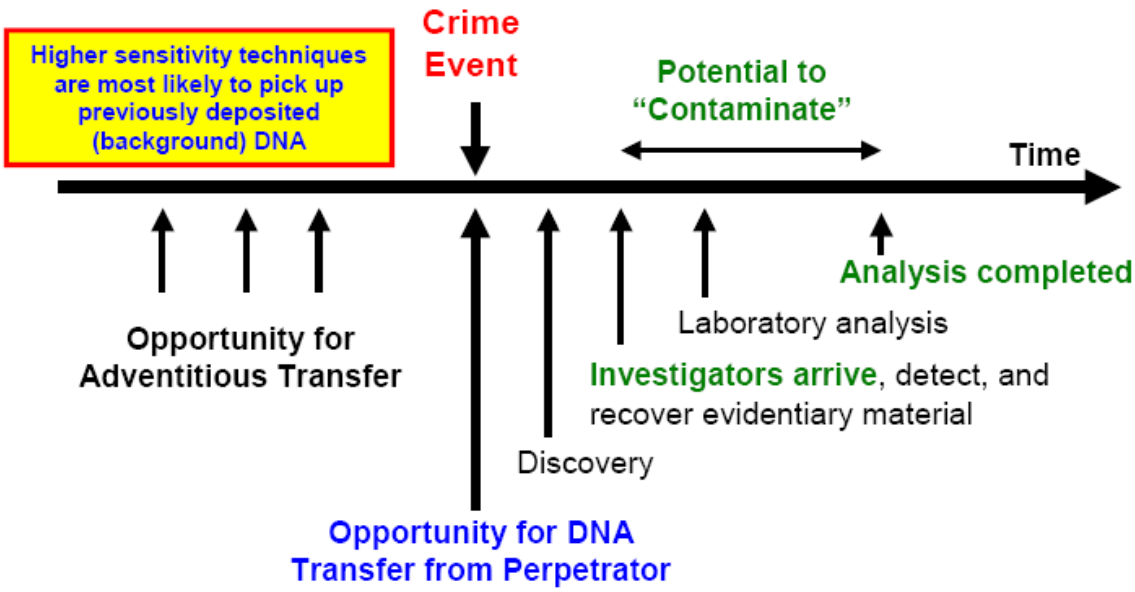

Figure 1.7 – A timeline indicating scenarios of DNA transfer pre and post crime event. LCN is capable of detecting lower thresholds of DNA, and possibly DNA transferred to items prior to a crime event. Informed comment can be made about transfer of DNA originating from certain substances such as blood or semen. However, it is much more difficult to provide comment on cell-free DNA, or low levels of DNA where limited contact may have occurred. Higher amounts of DNA present (nanograms) typically reveals greater contact or pressure between item and DNA source. The potential to contaminate evidence occurs post crime event.

Info. Box 1.2

Important LCN cases.

These cases illustrate the highly sensitive nature of the LCN technique.

Sean Hoey v. R

LCN was used to successfully generate a DNA profile from wires associated with a car bomb that killed 29 people and injured 220 others in Omagh, Northern Ireland, on 15 August 1998. The LCN profile matched Sean Hoey, a known member of the Real IRA. During the trial of Hoey (2007), questions were raised as to whether LCN is reproducible. By its very nature, it is not reproducible and Mr Justice Weir ruled the prosecution's evidence did not meet the required standard. The judge therefore removed DNA as part of the evidence, leading to the exoneration of Hoey. Hoey was later convicted of all murders in a civil trial.

Reed & Reed v. R

The appellants were convicted in August 2007 of the stabbing murder of Peter Hoe, on the basis of an analysis of LCN DNA profiles as well as other evidence. Appeals to this case have raised issues with the LCN process, including its lack of validation, limited research, absence of protocols, disputes of interpretation and the scope of the evaluation. Professor Allan Jamieson, Dr Bruce Budowle, and Dr Adrian Linacre, all holding extensive knowledge of LCN, provided the Court expert witness statements. The appellants prior to the hearing of the appeals abandoned the appeals regarding the reliability of LCN. Following further DNA testing by Dr Budowle, it was accepted that the appeal could no longer be pursued on the basis of the reliability of the LCN process. It is also worth mentioning that there was never a challenge to the fact that the profiles obtained on the knife handles matched the profiles of the appellants.

The appeal then shifted to the evidence about transfer of DNA and the various explanations that had been given by the prosecution's expert, arguing that this went beyond what was proper for an expert witness. The issue was if evidence could be admitted on the possibility of how the DNA came to be on the knife handles, and if those possibilities could be evaluated. The Court held that there was nothing wrong with the expert giving some evaluation of each of the possibilities of the circumstances of transfer and that this was indeed essential. However, the Court agreed that the expert witness went too far when she expressed the opinion that the appellants were *"handling the knives at the time when the handles broke"*, as this was not based on a reliable scientific basis. See Figure 1.7 illustrating the issues with DNA transfer.

Peter Falconio Murder: South Australia

Peter Falconio was a British tourist who disappeared while travelling with girlfriend Joanne Lees, in the South Australian outback during July 2001. Falconio's body has never been found and he is presumed dead. Bradley John Murdoch was convicted of his murder in December 2005 after LCN generated a DNA profile from the cable ties used around Joanne Lees wrists, that later found to match a DNA profile from Murdoch.

Info. Box 1.3 Admissibility of evidence based on new or novel methods in the Court.

The Daubert Standard

A Daubert standard provides a rule of evidence over the validity and admissibility of expert testimony conducted before a judge. The opposing counsel may challenge the evidence by raising a Daubert motion and the expert is required to demonstrate that their methodology and reasoning are scientifically valid and can therefore be applied to the facts of the case.

There are three U.S Supreme Court cases that articulated the Daubert standard. The phrase originated from the 1993 case *Daubert v. Merrell Dow Pharmaceuticals*. *Daubert v. Merrell Dow Pharmaceuticals*, Supreme Court held that Rule 702 of the Federal Rules of Evidence superseded Frye as the standard, incorporating a flexible reliability standard and articulating a new set of criteria for the admissibility of scientific expert testimony.

The second case, *General Electric Co. v. Joiner*, which held the judge may exclude expert testimony when there are gaps between the evidence relied on by an expert and his conclusion.

The third case, *Kumho Tire Co. v. Carmichael*, which held the judge's gatekeeping function identified in Daubert applies to all expert testimony, including non-scientific.

The Frye standard is also a test to determine the admissibility of scientific evidence derived from a new or novel scientific theory or methodology. The test stipulates expert opinion based on a scientific technique is admissible only where the technique has gained 'general acceptance' supported by a body of knowledge within the relevant scientific community. The Frye standard is limited in that it is essentially a 'counting heads' test that does not require the judge to understand the new or novel scientific theory or methodology presented to the courts. Although Frye and Daubert are not substantially different, Daubert's key subject is the scientific validity, the evidentiary relevance and reliability of the principles that underlie a proposed submission, with the focus solely on principles and methodology, not on the conclusions they generate.

The Queen v. Bonython

This case brought to question the qualifications of a witness, Sergeant Daly, to express his opinion on handwriting and the identification of signatures, and if his opinion is admissible in the Court. The Judge ruled the question regarding Sergeant Daly's expertise, designed to establish that the materials upon which the witness formed his opinion were inadequate, related to the weighting of the opinion and not to the admissibility of the opinion. A witness may give evidence only as to matters observed by him or her. Opinions are not admissible. The exception to this is the opinion of an expert. An expert witness must prove that the body of knowledge or experience which is sufficiently organised or recognised to be accepted as a reliable body of knowledge or experience are not, or are not wholly, within the within the knowledge or experience of ordinary persons. The judge must be satisfied that the witness possesses the necessary qualifications, whether they are from study, experience or both. In this case, the witness was able to satisfy the Judge of his knowledge, and was considered an expert witness.

LCN also presents interpretational issues: more extreme heterozygous peak imbalance, increased stutter, and increased laboratory based contamination (or allelic drop-in). All samples amplified using 34 cycles are processed in duplicates or triplicates, counting the alleles that appear twice, creating a consensus profile to assist with profile interpretation (Figure 1.8). Consensus profiles however, may also cause important data to be discarded from the final resulting profile if alleles are not observed in multiple replicates (Table 1.1). The incidences of increased artefacts in low-level DNA samples compromise the quality of the profile. The quality of a DNA profile is typically based on the number of loci, in which alleles are present, as well as the height based on relative fluorescence units (RFU) value of those alleles. With low levels of template DNA, allele peak heights fall and alleles begin to drop-out; making it difficult for an analyst to interpret the results especially when there may be more than one DNA contributor to the sample (mixed profile).

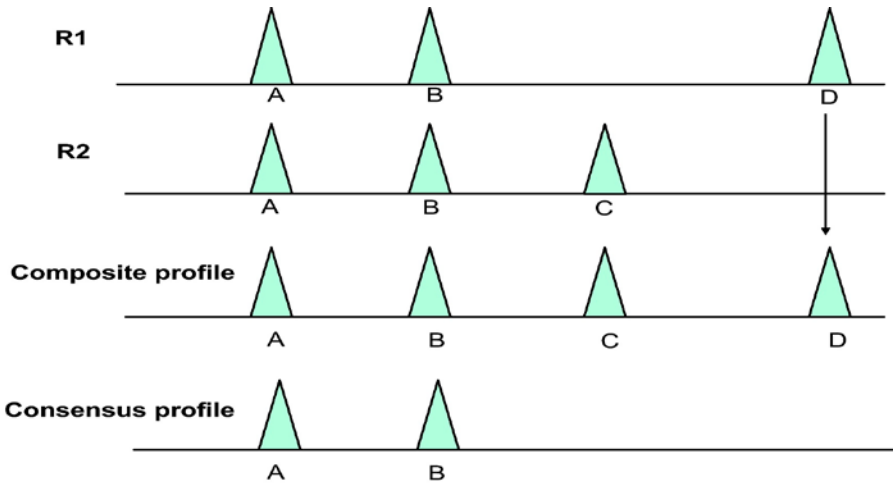

Figure 1.8 – Understanding the difference between composite and consensus profiles by comparing two replicates, R1 and R2. The consensus profile only contains alleles A and B as they appear in both replicates, whereas the composite profile contains all alleles (A, B, C and D) observed in both replicates. *Figure source: Bright [219]*.

Table 1.1 – A hypothetical example of a replicated sample showing the consensus profile. Observed donor alleles may be discarded as unconfirmed and not used as evidence with the consensus method (D8, allele 13). *Table derived from Cowen [220]*.

	AMEL	vWA	TH01	D8	FGA	D21
Replicate 1	X	15, 17	6, 9	10, 13	–	28, 31, 32
Replicate 2	X	14, 15, 17	6	10, 11	20	28, 31
Consensus	X, F	15, 17	6, F	10, F	F, F	28, 31
Unconfirmed donor alleles				13, 11	20	
Drop-in		14	9			32
Donor Profile	X, X	15, 17	6, 6	10, 13	20, 23	28, 31

The issues discussed surrounding trace DNA decrease the confidence of the analyst to correctly interpret a resulting profile, and why some laboratories are opposed to processing trace evidence. The value of trace DNA in an investigation is viewed differently depending on its application. It can be highly significant in terms of intelligence applications [131], where partial profiles are typically generated, they can aid in the inclusion or exclusions of a suspect. However, the weighting or value of trace DNA is viewed to decrease significantly if it is to be relied upon as evidence in a court of law [124]. It should also be noted that although analysis errors are rare due to contamination, they are possible and can have very serious consequences. For example, six murders were incorrectly linked to a hypothesised unknown female serial killer dubbed the "Phantom of Heilbronn" or the "Woman Without a Face" after DNA evidence linked crime scenes in Austria, France and Germany from 1993 to 2009 [221]. The source of the DNA was eventually found to have already been present on the cotton swabs used for collecting DNA samples, contaminated accidentally by a woman working at a factory in Bavaria. Human error and sample contamination are the most common cause of error rates in relation to the laboratory process [131], and highlights the need to investigate all aspects of the analysis process to reduce the number of contaminations and errors made.

1.3 Direct PCR

The process of direct PCR enables a DNA profile to be generated from a sample without the use of the extraction step, the sample instead is placed directly into the PCR reagents and then amplified. In microbiology, this technique is commonly known as 'colony PCR', and has been widely used since the early 1990s [222-224]. Colonies of bacteria yeast are directly amplified with specific primers as a rapid test to determine if the cloning process was successful [225-228]. In forensic science, existing standard operating procedures describe the necessity of extraction methods to remove potential PCR inhibitors, thus allowing the downstream processes to occur. In regards to trace DNA samples, however, where the starting DNA amount may already be incredibly low, the potential for DNA to be lost through sample collection and the extraction process can be highly detrimental as it could dramatically reduce the likelihood of obtaining a meaningful DNA profile [229]. Significant resources are often used to process trace DNA samples, with commonly submitted samples such as handled items typically returning the least successful profiles [230]. The LCN technique was developed to combat the low success rate of obtaining meaningful data from trace DNA samples, but as previously outlined LCN has its own set of disadvantages associated with the validation of the technique, as well as the analysis and interpretation of the results.

To use direct PCR with forensic trace DNA samples would mean that the downstream processes are open to the effects of inhibition, however, common forensic inhibitors such as haem compounds from blood, bile salts and complex polysaccharides, urea, and collagen and certain dyes found in clothing, are not commonly present in touch or trace DNA samples [231]. The type of extraction method used is also known to play a significant role in the loss of template DNA due to number of tube transfers required [30, 31]. Therefore, circumventing the extraction process would save time and money by speeding up the processing procedures and potentially increasing the DNA template of challenging and difficult samples. It is hypothesised that during direct or colony PCR, the initial polymerase activation step (typically 95°C) is hot enough to disrupt the membranes of the cells, releasing the DNA into the master mix making it available for amplification [18, 232]. Similarly, any cell-free DNA present on the surface of touched samples could also be released into the PCR mix during this direct process [31, 215, 232].

Direct PCR was first investigated in forensic science in 2010; swabs, cotton, nylon, polyester and denim fabrics that had been in direct contact with a person were amplified directly (placed within the PCR mastermix) following manufacturer's instructions [18]. Complete and partial DNA profiles were obtained from these samples without initially extracting the DNA, reducing the processing time required by up to two hours. Circumventing the extraction process resulted in no tube changes,

thus reducing the chances of DNA contamination from external sources, as well as reducing the amount of DNA lost due to tube retention. As more DNA was made available to the amplification process, the sensitivity of the test improved without the need to alter the manufacturer's protocol by increasing the number of cycles [18]. The overall improved time and cost reduction, as well as the increased sensitivity and results of these difficult trace samples is a positive and promising step forward in the forensic science community. These conclusions were further supported by comparative studies of direct PCR to traditional DNA extraction methods where direct PCR consistently generated higher quality and more complete DNA profiles [232, 233]. The studies found that the type of extraction technique used as well as the type of DNA substrate used, directly influenced the amount of DNA lost during the collection and amplification steps, subsequently affecting the generation of a DNA profile.

1.4 Aims of Thesis

This thesis aims to further investigate the use of direct PCR in forensic casework by exploring a wider range of forensic relevant substrates and samples, optimisation and validation of the technique, addressing limitations and concluding with implementation recommendations.

Optimisation of direct PCR will include testing different polymerases and PCR buffer constituents, to determine the best combination to overcome any potential inhibitors present on the samples. Due to the nature and variation of crime scenes and sample types, samples may come into contact with inhibitors ranging from components found in whole blood (such as haem) to soils and dirt, dyes found in fabrics, or other chemicals (such as house hold cleaners). Surface substrates, such as brick, glass, plastic, or fabric type may also affect the efficiency in which DNA is collected, transferred or extracted due to their particular characteristics. The efficiency of DNA collection may be further inhibited by the method of extraction and concentration used when processing evidence.

To reduce the effects of these variables and maximise the potential of the direct PCR technique, this thesis will focus on trace evidence sample types that are known to be difficult in consistently producing useable profiles, and samples that also lack potential inhibitors to ensure there is little to no processing of the samples prior to amplification.

Chapters of this thesis consist of published articles, short communications or technical notes, casework involvement, conference proceedings, or data presented at conferences in the form of posters or abstracts, with all remaining data and discussion formatted for submission to scientific journals. Chapters also contain manuscripts formatted to an appropriate journal, but are not yet ready for submission; these manuscripts may require additional data or research to be collected outside of this PhD candidature. An additional two manuscripts are currently under review. Each chapter will begin with a short preface to outline the data presented, followed by concluding remarks and appropriate appendices.

A method for the DNA quantification of direct PCR samples

Use of direct PCR on trace evidence samples

Case 1 – Seizure of Methamphetamine in South Australia

Direct PCR Enhancement

2.1 Preface

To identify the capabilities of direct PCR in a forensic setting, different steps of the DNA analysis process were investigated further for areas of improvement. Firstly, *section 2.2* explores the efficacy of DNA extraction methods. As the DNA extraction and isolation step is skipped during direct PCR, it is important to determine how this step may impact on the resulting DNA profiles of trace evidence samples. The results are also dependant on variables such as sample type, collection method and extraction method used. Three common extraction methods were used, keeping other variables constant, to determine how much DNA is lost during the process, which method produced consistent results, and which method was most suitable for trace evidence samples. Following the extraction step, PCR buffer constituents were explored in *section 2.3* to identify additives that may assist in overcoming PCR inhibition during the direct process. Known PCR enhancers were used in varying combinations and concentrations between two commonly used human identification kits, with improvements determined by an increase in the quality and number of alleles obtained, as well as the intensity or height of the resulting DNA profiles. *Section 2.4* applies the preliminary findings of extraction kit efficacy and buffer enhancements to a wider range of forensic relevant samples, as well as determining the limit of detection for direct PCR methods. To address concerns that may arise over the inability to quantify DNA during direct PCR, as the extraction step (and consequently quantification step) is skipped, *section 2.5* investigates a mathematical-based method to quantify the input DNA of samples post amplification. The knowledge obtained throughout these investigations enabled the direct PCR technique to be applied to difficult casework samples *in section 2.6*. Results were obtained from a variety of samples where traditional methods had failed to produce DNA information.

[2]*Forensic Science South Australia, Adelaide*

Dear Editor,

In forensic science, the occurrence of trace DNA at crime scenes is common and sometimes may be the only evidence available to an investigation. Trace evidence presents its own set of difficulties; too little DNA will result in a partial profile, providing reduced significance, or more commonly no profile at all. The extraction method is the first step involved in DNA analysis, and is open to variation in DNA yield depending on the method used. It is an important step for the isolation and purification of DNA as it aims to remove inhibitors permitting downstream processes to work effectively. This process typically involves several wash steps and tube changes, each allowing for DNA retention to tubes and pipette tips, resulting in the loss of information. Extractions routinely work well for certain sample types such as blood, tissue and saliva where a large number of cells are typically present. Trace evidence such as single hairs, fibres, or swabs of touch DNA routinely fails to produce DNA profiles of significance. This poses great difficulty for investigations as these are often found at crime scenes and may be the only physical evidence available. We report on the retention and loss of DNA using three commonly used extraction methods in forensic analysis. DNA mass was measured prior and post extraction using the Qubit® 2.0 Fluorometer, and compared to assess the percentage lost.

Three common extraction methods were tested to determine the average loss of DNA from each: QIAamp® DNA Micro Kit (QIAGEN), DNA IQ™ System (Promega) and Chelex®. Previously extracted DNA (from buccal swabs using QIAGEN Micro Kit) was quantified on a Qubit® 2.0 Fluorometer (Invitrogen™) and used as the control in this experiment. Control DNA ranging from 35 – 39 ng was used as the starting concentration for each extraction. Extractions were performed following the manufacturer's instructions for each kit and were eluted in a final volume of 30 μL for the DNA Micro Kit and 100 μL for Promega IQ™ and Chelex®. Chelex® extraction involved adding 200 μL of 5 % Chelex® to the DNA in a 1.5 mL tube and incubating at 56 °C for 20 mins

with shaking, followed by 100 °C for 8 mins with shaking. Sample was centrifuged at max speed (13000 g) for 3 mins. Liquid was removed without disturbing the Chelex® pellet and transferred into a new sterile 1.5 mL tube. Extractions were repeated eight times for each method used. Each extraction sample was quantified using the Qubit® following manufacturer's instructions, using 10 μL from each sample for quantification. The quantification results were compared against the initial input DNA to determine percentage lost.

DNA loss ranged from 36.5 % to 96.9 % across all methods, with QIAamp® performing the best with the lowest average of 53.4 % DNA loss (Table 1). Promega IQ™ and Chelex® were highly consistent with the results obtained, showing approximately 3 % variation between the highest and lowest losses observed. Although the results varied quite significantly for the QIAamp® Micro Kit, it still out-performed the other kits with the highest DNA loss obtained (82.6 %) being less than the lowest percentages observed for the other two kits (89 % and 94.3 %). These three common methods of DNA extraction are very inefficient with their average loss ranging from 53.4 – 95.8 %. The currently used extraction methods are not ideal for trace evidence samples where minimal initial DNA is present, and methods should be adjusted for trace evidence samples in order improve results and reduce time and money wasted on the inefficiency of current methods.

Table 1: DNA lost from standard extraction methods

DNA Extraction Kit	Starting Mass (ng)	Average Final Mass (ng)	Average Percentage Lost (%)	Lowest/Highest Percentage Observed (%)
Promega IQ™	36	1.5	95.8	94.3 / 96.9
QIAamp® Micro	39	17.1	53.4	36.5 / 82.6
Chelex®	35	3	91.5	89.0 / 92.3

Abstract

We report on the significant improvement of DNA profiles by the addition of standard chemicals to the polymerase chain reaction (PCR) buffer provided in commercially available human identification kits. Triton® X-100, BSA and DMSO were added to the PCR buffer, both singly and in combinations, provided in the AmpFλSTR® Profiler Plus® or NGM SElect™ kit (Life Technologies, Victoria, Australia). PCRs were performed in 0.2 mL thin walled tubes following the standard protocol for a 25 μL volume reaction, following all manufacturers' conditions for amplification. PCR products were analysed using a 3130*xl* (ABI) and GeneMapper® ID v3.2 (Life Technologies) with a threshold of 50 relative fluorescence units (RFU) for allele assignment. The average RFU was calculated for each profile obtained where the buffer was adjusted. The values were compared against positive and negative controls where no buffer adjustments were made. A 70 % increase in RFU value was observed with the addition of a combination of DMSO with either BSA or Triton® X when using Profiler Plus®, and a 35.7 % increase was observed with the singular addition of BSA for NGM SElect™. Our data indicate the clear improvement in the quantity of profiles obtained across both kits, offering a fast and cost effective way to boost the results. This enhancement may be beneficial in cases where limited or degraded DNA is present, offering further assistance in difficult investigations.

Key words: forensic science, DNA typing, direct polymerase chain reaction, buffer enhancement, human identification

Dear Editor,

We show how the addition of standard chemicals to the PCR buffer provided in commercially available STR kits improve the quality of DNA profiles by significantly increasing the RFU value. The factors that affect the quantity of PCR product include the initial quantity of DNA template and the presence of inhibitors of the amplification and the buffer components. Triton® X-100, BSA and DMSO have been shown to increase the amount of PCR product produced and overcome inhibitors to the amplification [1, 2] and hence these standard materials were added to the PCR buffer, both singly and in combinations, provided in two commercially supplied STR kits, and the resulting data analysed. Although this experiment uses control DNA, in which there are no inhibitors present, the effect of each buffer adjustment should be documented first to indicate which addition will potentially have the greatest impact for the use of more difficult sample sets such as trace DNA or overcoming inhibitors in direct PCR.

PCRs were performed using either the AmpFλSTR® Profiler Plus® or NGM SElect™ kit (Life Technologies, Victoria, Australia) in 0.2 mL thin walled tubes following the standard protocol for a 25 μL volume reaction. Positive and negative controls acted as the standards in this experiment with no additions made to their buffers. Final concentrations of Triton® X (0.004 %), DMSO (4 %), BSA (0.008 μg) were added to PCR buffers in the following combinations: Triton® X (T), DMSO (D), BSA (B), B/D, T/D, and T/B/D. All PCRs contained 1 ng of control DNA (2800M, Promega, Victoria, Australia). Amplification conditions for all samples followed the manufacturer's instructions at 29 cycles using a GeneAmp® 9700 96-well thermal cycler (Life Technologies). PCR products were analysed using a 3130*xl* (ABI) and GeneMapper® ID v3.2 (Life Tehcnologies) with a threshold of 50 RFU for allele assignment. The average RFU value of a profile (9 loci Profiler Plus® or 15 loci NGM SElect™) for each modified PCR was compared against the average RFU value of the standard (positive control) to determine the effect of the buffer adjustments. For each kit, each buffer addition (six combinations), and positive and negative controls was set up three times and run in triplicate on the 3130*xl*, resulting in a total of 144 samples used in this experiment. No other combinations were trialled in this experiment.

The effect of the buffer adjustments is illustrated in Figure 1, which shows the increase in RFU values for both STR kits using the additions to the buffer. PCR products obtained using the Profiler Plus® kit showed the greatest increase in RFU value across all buffer adjustments compared to the NGM SElect™ kit. The combinations of BSA/DMSO and Triton® X/DMSO resulted in an RFU increase of approximately 70 % across all nine loci. All RFU increases using this kit were statistically significant ($p = < 0.001$). Using NGM SElect™, the average RFU increase

ranged from 1.4 % to 35.7 %. The only statistically significant increase was observed with the singular addition of BSA ($p = < 0.05$). Overall, an increase in RFU value was seen for each addition and combination across both kits.

Our data indicate the clear improvement in the quantity of STR products produced with the addition of a combination of DMSO with either BSA or Triton® X when using Profiler Plus®, and the addition of BSA for NGM SElect™. This offers a fast and cost effective way to boost the quality of results obtained for these kits. Such an enhancement may be crucial in cases where there is trace DNA. Direct PCR incorporates limited DNA template into the buffer to enhance the profiles obtained [3, 4], coupled with the buffer additions outlined in this study could further aid difficult investigations.

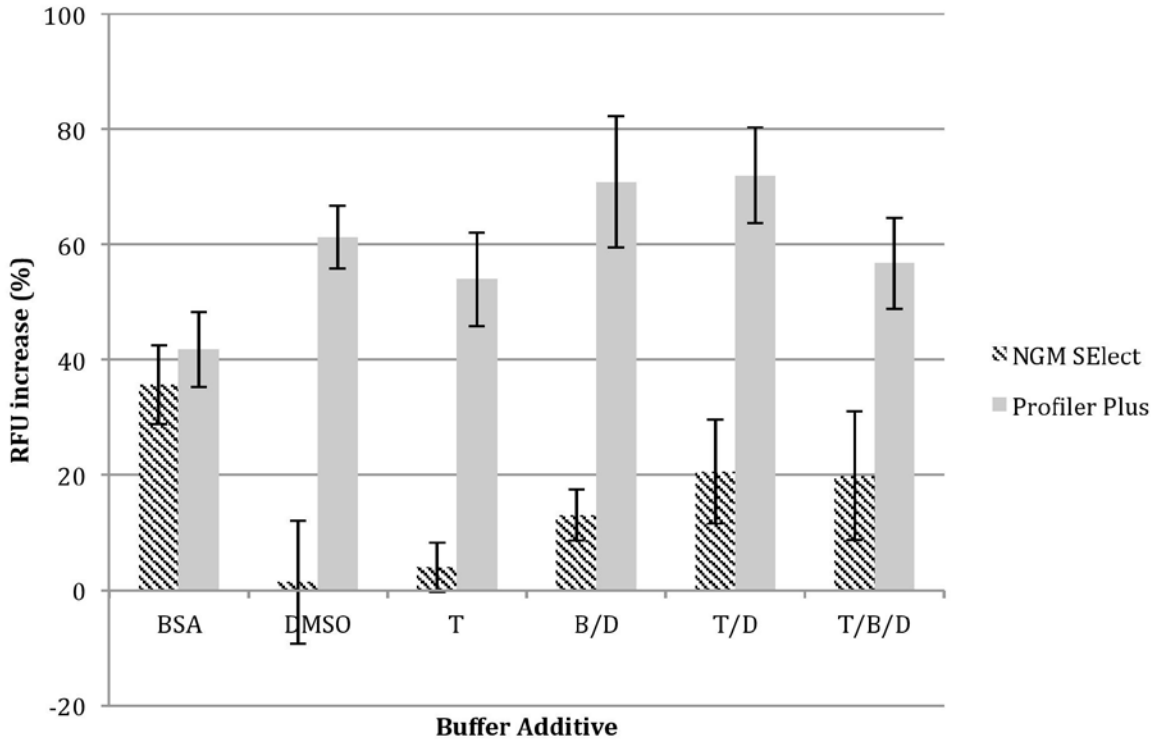

Figure 1. Known buffer enhancers BSA, DMSO and Triton® X were added individually and in combination to two standard STR kit buffers. The average RFU value across all loci for a sample was compared against the RFU value of the positive control sample (no buffer additions). The increase in RFU value from the positive control was recorded in per cent (%) and shown above across all enhancement types for both STR kits. Standard Error (SE) bars are displayed for n = 9 replicates of each buffer additive.

ABSTRACT

Direct PCR is fast becoming a popular method in forensic science due to the advantages of saving time and money in the lab while increasing the probability of obtaining substantial results has a positive rippling effect. A laboratory is able to reduce the time spent on processing trace DNA samples, which can lead to investigators receiving important information in a timely manner that may not have been possible using standard methods. This study highlights the benefits of direct PCR in forensic casework by analysing trace and touch DNA on a range of substrates and exploring the loss of initial DNA due to extraction.

1. Introduction

Direct PCR can generate full STR DNA profiles from trace samples without using extraction or quantification processes [1]. A previous study reports a loss of up to 76% of initial DNA due to the multiple wash steps and tube changes involved in the extraction process [2], ultimately affecting the quality of the DNA profile obtained. Samples containing less than 100 pg are considered to be trace DNA [3], and generally require an increase to 34 cycles to obtain meaningful data. This study highlights direct PCR sensitivity and the ability for trace DNA to be amplified without the need to increase cycle number or modify current protocols to obtain meaningful data. A direct PCR approach is a viable option for the future of trace DNA recovery and analysis for forensic science purposes, vastly improving efficiency, sensitivity and the quality of results.

2. Materials and method

2.1. Determining loss of DNA via extraction

QIAamp DNA Micro Kit (QIAGEN) and DNA IQ™ System (Promega) were used to determine the average loss of DNA. A total of 20 ng of control DNA (2800 M, Promega) was used as the starting concentration for each extraction. Extractions were performed followed the manufacturer's instructions for each kit and were eluted in a final volume of 30 μL for maximum DNA yield. Extractions were repeated five times for each kit used. Each extraction sample was quantified on a Qubit® 2.0 Fluorometer (Invitrogen™) following manufacturer's instructions, using 5 μL from each sample for quantification. The quantification results will be used to determine the loss of DNA. The quantification results will be compared against the initial input DNA to determine percentage lost.

2.2. Direct PCR

DNA extraction and quantification are bypassed. The range of samples tested include: single hairs in anagen and telogen growth phases, fibres from swabs used on plastic and glass surfaces, single fibres from clothing, latex gloves, and a range of plastic tapes. Each sample is placed directly into a prepared 0.2 mL thin walled tube containing 25 μL of reagents from either the AmpFℓSTR® Profiler Plus® or NGM™ kit (Life Technologies, Victoria, Australia). Sample sizes were approximately 5 mm in length for hair and fibres, and 5 mm × 5 mm for tapes, swabs and gloves. Amplification conditions for all samples followed the manufacturer's instructions at 29 cycles. PCR was performed on a GeneAmp® 9700 96-well thermal cycler (Applied Biosystems) following manufacturer's instructions. PCR products were analysed using a 3130*xl* (ABI) and GeneMapper® ID v3.2 with a threshold of 50 RFU for allele assignment.

2.3. Limit of detection for PCR

A series of positive control (DNA 2800M) samples were created to determine the lowest concentration of DNA needed to produce a

Table 1
DNA lost from standard extraction.

DNA extraction kit	Starting concentration (ng)	Average final concentration (ng/30 μL)	Average percentage lost (%)
Promega IQ	20	3.3	83.5
QIAGEN Micro	20	5.7	71.5

full DNA profile. Positive control PCRs were set up in triplicates in the following DNA concentrations: 0.05 0.1, 0.2, 0.3, 0.4, 0.5, 0.7, 0.8, 0.9, and 1 ng. Each sample was amplified and analysed in the same way as the direct PCR method, except 1 μL of each DNA concentration was used.

3. Results and discussion

3.1. Loss of DNA

The QIAGEN Micro DNA extraction kit yielded a higher DNA concentration overall, retaining on average 28.5% of the original amount. Although the QIAGEN kit performed better, both methods lost a substantial amount of DNA ranging from 71.5% to 83.5% (Table 1). Validated STR kits recommend using 1 ng of input DNA to optimise PCR, thus from a 30 μL elution, 9.1 μL would be required from the Promega kit and 5.3 μL from the QIAGEN kit. The average DNA lost when combining both kits is 77.5%.

3.2. Direct PCR

Profiles 'up-loadable' (≥12 alleles) to the Australian National DNA Database were obtained from the following substrates:anagen and telogen hairs, single fibres from worn or touched fabric, plastic tape, and single fibres from a range of swabs used on glass and plastic surfaces. Less than 12 alleles were observed from latex glove samples.

3.3. Limit of detection

Using standard PCR cycling conditions, the lowest initial template concentration of DNA at which a full DNA profile could be obtained was 100 pg. With a reduction to 50 pg, up-loadable profiles were obtained, with some allelic drop-out occurring. A single diploid human cell contains ~6 pg of DNA [4], therefore 100 pg equates to ~17 cells (assuming there is no contribution from cell-free DNA). If a sample lost 80% of its DNA via an extraction method (based on a 30 μL elution), a starting concentration of 500 pg (~84 cells) is needed in order to obtain a template of 100 pg for the PCR, and hence a full profile. However, most kits allow up to a maximum of 10 μL of input DNA for a standard 25 μL reaction. Therefore, to maintain this reaction volume size, the true starting DNA concentration using standard extraction procedures needs to be approximately 1.5 ng (250 cells), with an extraction loss no greater than 80%.

4. Conclusion

As DNA is not lost during an extraction process when using direct PCR methods, only 17 cells are required to obtain a full STR profile compared to 250 cells when using standard DNA extraction methods; thus making direct PCR up to ~15 times more sensitive than conventional extraction methods. No modifications are made to STR kit protocols allowing for quick and easy implementation into forensic laboratories. The results obtained by this laboratory are encouraging when typing trace amounts of DNA, and potentially are a vast improvement when compared to current industry methods.

Abstract

We report on a method to quantify the DNA template used in direct PCR amplifications based on the resulting magnitude of the allele peaks generated. Direct PCR has the advantage of using all genetic material available from a sample thus increasing the information obtained from trace evidence. A potential criticism of direct PCR is that quantification of the initial starting template DNA is not possible. To counter this, we demonstrate a method for determining the starting DNA concentration based on the profile obtained. We start on single source pristine samples ranging from 0.05 ng to 1 ng to mimic the range of DNA concentrations likely to be encountered in casework. We proceed to casework samples and demonstrate how to take into account complicating factors such as degradation, inhibition and contribution from multiple sources. The resulting method demonstrates how, using peak heights from the DNA profile, the original template DNA can be calculated with a desired quantile of interest allowing an estimate of the number of cells from a sample processed via direct PCR to be provided.

Key words: DNA profiling, direct PCR, DNA quantification, reverse quantification, confidence intervals

Introduction

The benefits of direct PCR have been greatly highlighted by its successful application to trace DNA samples, such as touch DNA, where conventional DNA extraction prior to quantification and amplification failed to routinely generate a DNA profile[1-7]. The technique is gaining this interest due this increase in sensitivity by omitting the standard DNA extraction process, with the associated benefits or reduced time and costs. DNA extraction processes typically result in an 80 % loss of starting DNA[8, 9] such that at the conclusion of the process, the subsequent quantification may indicate that there is insufficient genetic material to generate a DNA profile. DNA profiles can be generated from single hairs[2], and touch DNA when submitting the same samples to DNA extraction leads to very little chance of generating a meaningful DNA profile[6]. While direct PCR has these clear advantages there are some disadvantages such as lacking in reproducibility and the circumventing of the quantification step. Quantification of the mass of DNA in an extract is a requirement of the SWGDAM recommendations[10].

Quantification is a common step in generating a DNA profile as it informs the analyst how much DNA has been recovered from an extraction and hence the mass of DNA to be added to a PCR; this being typically 1 ng to 500 pg using commercially available STR DNA profiling kits. It also has the dual purpose of providing some important investigative information to analysts as to how much cellular material was recovered initially. Such information may assist the analyst in assessing whether there was a large amount of DNA present or only trace levels[11]. A method of DNA quantification for direct PCR would allow for estimations to be made on the level of cellular material found on substrates prior to direct PCR typing.

The level of fluorescence in a treated DNA sample can be used to indicate how much DNA is present[12, 13]. Conventional quantification methods such as RT-PCR and the Qubit® Fluorometer are based on the measurement of fluorescent probes against known standards[13, 14], whereas continuous

systems of DNA interpretation use peak height or area, measured in relative fluorescent units (RFU), information to determine the quantity of DNA in their calculations[15].

In the downstream process of DNA analysis, during capillary electrophoresis (CE), the measurement of laser-induced fluorescence of dye-labelled PCR products is used to produce a DNA profile with peak heights measured in RFU. There are several factors that affect fluorescence emission and the RFU value obtained. Using validated kits and techniques, these factors are: initial DNA available in a PCR, environmental conditions such as temperature, pH and salt concentration[16], and DNA sample factors such as degradation, inhibition, locus amplification efficiency and contribution of DNA by multiple individuals. An expectation is an approximately linear correlation between DNA mass and the RFU value should be observed within a single CE run. A linear correlation between these two factors would allow for calculations to be made of DNA mass based on the resulting RFU value. Here we report on a method to estimate the mass of the initial DNA template used in a direct PCR amplification using single source samples. We start with simple, single source, pristine samples and then demonstrate how to adapt the method for more complex situations.

Materials and Methods

DNA Amplification – pristine DNA

DNA was amplified using the NGM SElect™ kit (Life Technologies, Victoria, Australia). This kit amplifies 16 STR loci plus amelogenin using 29 cycles of amplification, as validated by the manufacture if starting with 500 pg of DNA as template. A known mass of starting DNA 2800 (Promega, Victoria, Australia) template was used ranging from 0, 0.05, 0.1, 0.2, 0.5 and 1 ng of DNA. Each series of known mass of DNA (0 – 1 ng) was prepared three times for a total of 18 samples. Each sample was prepared in a 0.2 mL thin walled tube containing 25 µL of reagents following the manufacturer's instructions. A total of 29 PCR cycles was performed on a GeneAmp® 9700 96-well thermal cycler (Life Technologies) following manufacturer's instructions. PCR products (1 µL) were

combined with 0.5 µL Liz 500™ (Life Technologies) and separated using a 3130*xl* Genetic Analyser (Life Technologies). The data were analysed using GeneMapper® ID v3.2 (Life Technologies) with a threshold of 50 RFU for allele assignment. Samples were run in triplicate on the 3130*xl* for a total data set of 54 complete DNA profiles (nine data series of 0 – 1 ng).

DNA Amplification – Casework DNA samples

100 samples were chosen from criminal cases at Forensic Science SA (FSSA). DNA samples were extracted using the DNA IQ™ system (Promega), and PCR amplifications carried out on a 9700 using GlobalFiler™ (Thermo Fisher Scientific) as per manufacturer's instructions. Amplification fragments were resolved using a 3130*xl* Genetic Analyser and analysed in GeneMapper® ID-X to obtain peak height information for each profile using a detection threshold of 30 RFU.

Reverse Quantification Analysis

A method was required that could take into account complicating factors that affect peak height such as degradation of DNA, PCR inhibition, locus amplification efficiencies and contribution of DNA from multiple individuals. Combinations of these points (particularly the contribution of DNA from multiple individuals), means that the heterozygote or homozygote status of any individual allele in the DNA profile can be uncertain. We employ the idea of Total Allelic Product (TAP) when considering fluorescence. TAP theory suggests that from a starting amount of template DNA we expect a total amount of fluorescence, however this will be split across allele and stutter peaks. The same theory can be applied to mixed DNA profiles deriving from a number of individuals; we expect a total amount of fluorescence from this starting template, it will just be split across a number of peaks. To deal with this, we sum the heights of all peaks at each locus (which we call T_l for the *T*otal fluorescence at locus *l*). This means that the total template DNA is being considered, regardless of number of contributors, the presence of stutter artefacts or the heterozygous or homozygous nature of any particular peak.

Given T_l there is still the issue of accounting for degradation, inhibition and locus specific amplification efficiencies. There are a number of options that can be considered when regressing fluorescence against DNA concentration:

- Average over profile – ($T_{l,1}$) – This may overcome amplification efficiency imbalances across the profile
- Choosing the loci with the lowest molecular weight – ($T_{l,2}$) – This method should overcome the issue of degradation
- Choosing the loci with the largest T_l value – ($T_{l,3}$) – This method should overcome degradation and inhibition (important if the lower molecular weight loci are those that are affected by inhibition)

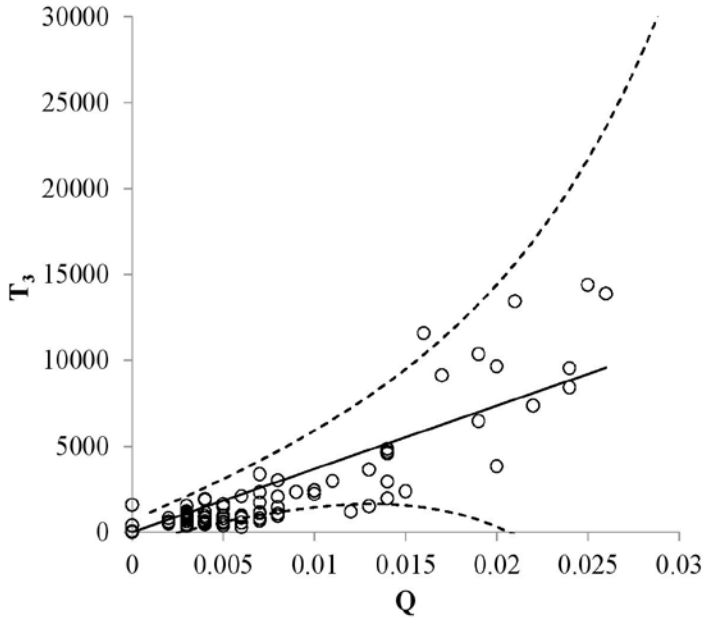
We trial each of these three methods by carrying out regression of DNA amount added to the PCR, Q, (in ng) against $T_{l,i}$, using R.

$$Q = \beta T_{l,i}$$

Note that the above regression forces the data through the origin as we assume that a DNA extract with no DNA would yield a profile with no peaks.

We first apply the regression to pristine data. We then split the 100 casework samples into two groups of 50. The first group we consider a training group, used to generate the regression parameter values and the second group we consider the test group, to which we apply the regression results. This was done for each of the three fluorescence measurement options in order to determine their portability across datasets. Q values of greater than 0.04 were omitted from the analysis as this corresponds to the point at which the peaks produced from PCR reach saturation on the 3130*xl*.

Heteroscedasticity was observed in the data with respect to *T* values, namely as *T* increased so too did the size of the residuals. We fit an exponential function to the standard deviation in T value for Q brackets of 0.005 and use this to plot confidence intervals from the regression.



T3 V Q showing regression line (solid) and 95% confidence intervals (dotted). Based on all casework data at this stage (training and test)

Results and Discussion

Pristine DNA

The three regression methods gave roughly equivalent results for the pristine data, although this is expected given that the pristine data was single sourced, non-degraded, no-inhibited and of known genotypic origin. The results of the regression are given in Figure 1, which shows the expected vs known DNA amounts and the 95% confidence interval on the estimation. The reverse quantification method relies on the assumption that a linear relationship exists between template DNA mass and the fluorescence of the resulting DNA profile. The DNA amounts estimated by the regression generally underestimated the amount of DNA in the 1 ng standard, which would be expected if it were subject to saturation, which affects the linear relationship between DNA amount and fluorescence.

Conclusion

Previously there has been no means of estimating the initial amount of DNA used in a direct PCR. The statistical method described in this study enables the calculation of the DNA mass. The data indicate a high correlation between DNA mass and average RFU value, allowing for DNA mass calculations to be made within a factor of 1.57 of the actual value at a 95% confidence level. Not only will this provide knowledge of how much DNA template was probably present in direct PCR sample, but it can help identify how much DNA was within a substrate prior to the amplification. It is noted that this preliminary study illustrates the potential for the accurate estimation of the quantification DNA present using single source DNA and therefore applicable to use with single hairs or areas where a single person has made contact with a substrate. The application would therefore be beneficial in processing touch and trace DNA from fingermarks, single hairs, and surface swabs as this technique provides an informative estimation of initial amount of template DNA. The estimate of quantification is accurate even at low levels of starting DNA. As the standards required to calculate the DNA mass of samples are equivalent to the positive and negative control samples of a PCR setup, no additional laboratory work is required to implement this technique.

2.6 Application

2.6.1 Case 1 – Seizure of Methamphetamine in South Australia

March 2013 saw 7.33 kg of pure methamphetamine uncovered by police in one of the state's biggest drug hauls, valued at more than AU $20 million. The drugs were discovered roadside when two men were acting suspiciously and drew the attention of police officers. The men were interrupted as they were digging up containers filled with the drug, as pictured in Figure 2.1.

Figure 2.1 – Several containers were discovered partially buried roadside in South Australia, containing a total of 7.33 kg of pure methamphetamine.

Although two suspects were arrested and charged following the find, a drug operation of this scale would involve a larger network of individuals. Forensic Science SA (FSSA) were tasked with processing the evidence in hopes of obtaining DNA profiles, and other valuable information, to link to the apprehended suspects, and possibly other suspects to the crime. Standard procedures were unable to provide meaningful DNA information from the evidence sampled. To obtain DNA from the evidence would be highly challenging, as many factors would impede the results. Firstly, DNA present on the containers pictured would most likely be found in trace amounts in areas such as the underside of the tape, particularly the tape ends. DNA present on the outside of the containers would be exposed to environmental elements such as bacteria in the soil and varying temperatures that contribute to DNA degradation. Lastly, a high percentage of DNA is lost to the extraction process, as mentioned previously.

South Australian Police were referred to the DNA laboratory at Flinders University by FSSA, due to the recent success and promising preliminary results the direct PCR technique had with trace DNA samples. A range of evidence samples was selected by Renée Blackie, Jennifer Templeton and Adrian Linacre, to be processed using the direct PCR method. Samples included empty containers and a range of adhesive tapes – identified on the tapes for further processing included several fibres and single hairs. Tapes and containers were also swabbed at various locations, with the fibres from the swabs processed directly. A total of 24 samples were processed.

Swab tips were moistened with 2 µL of pre-heated (50°C) Triton® X (Sigma-Aldrich) at 0.1 % concentration. Moderate to heavy pressure was used on samples. Swab tip fibres were cut directly into pre-labelled 0.2 mL thin walled tubes ready for processing. All samples were amplified using AmpFℓSTR® NGM SElect™ kit (Life Technologies, Victoria, Australia) in 0.2 mL thin walled tubes following the standard protocol for a 25 µL volume reaction. An additional 1 µL of AmpliTaq Gold® DNA polymerase was added to overcome inhibitors that may have been present. Amplification conditions followed the manufacturer's instructions at 29 cycles using a GeneAmp® 9600 thermal cycler (Life Technologies). PCR products were analysed using an ABI 3130*xl* Genetic Analyser (Life Technologies) and GeneMapper® v3.2.

Alleles were obtained from all 24 samples processed, ranging from 4 – 42 alleles, with 17 samples resulting in 10 or more alleles. As expected, due to the sensitivity of the technique, 14 profiles contained alleles from two or more contributors (casework item can be observed in Figure 2.2, with resulting profiles in Figures 2.3 – 2.7). All data obtained was forwarded to FSSA for further analysis.

2.7 Concluding Remarks

The investigation into each step of the DNA analysis process has enabled the direct PCR process to be enhanced and optimised to suit forensic relevant samples. The data obtained has identified that up to 97 % of DNA is lost to the extraction step depending on the method used. This extreme loss is highly detrimental when processing trace DNA samples, indicating a massive downfall in the current methods and that most commercial kits are not designed to process such samples. With the process circumvented, the DNA is not only retained for amplification, but there is less handling involved, decreasing not only time and costs, but risk of contamination. Buffer enhancements such as the addition of extra AmpliTaq Gold®, Triton® X, and DMSO has also shown to assist in overcoming inhibition, and enabling better DNA collection when using swabs.

Supplementary Material

a. The efficacy of DNA extraction methods in forensic science

Preliminary data

Two common buccal swabs, FLOQSwabs™ (COPAN) and Fitzco (Pathtech) were tested using the QIAamp® DNA Micro Kit (QIAGEN) following manufacturer's instructions to determine if a particular swab yielded significantly higher DNA concentrations and to provide control DNA for further testing. Using the Qubit® 2.0 Fluorometer (Invitrogen™), the FLOQSwab™ resulted in 39.45 ng of DNA and the Fitzco swab resulted in 35.25 ng of DNA.

Raw data

Three extraction methods were carried out following manufacturer's instructions, using control DNA obtained in the preliminary testing. Each extraction method was tested for eight samples.

Table 2a.1 – DNA lost from three standard extraction methods, showing final percentage lost for eight samples per extraction method.

Extraction Method	Input DNA mass (ng)	Recovered DNA mass (ng)	Percentage Lost (%)

c. A method for the DNA quantification of direct PCR samples, and limit of detection for PCR

Raw data

The following raw data sets were used to determine the limit of detection for PCR of the NGM SElect™ human identification kit, as well as the basis for the statistical quantification of direct PCR samples. Raw data for single hairs, fibres, and tapes can be found in the relevant chapters of this thesis.

Table 2c.1 – NGM SElect™ allele call and RFU value of positive control DNA samples at concentrations 50 pg, 100 pg, 200 pg, 500 pg and 1 ng. Replicate 1.

Introduction

In forensic science, trace DNA is common and sometimes may be the only evidence available to an investigation. Trace evidence presents its own set of difficulties; too little DNA will result in a partial profile, providing reduced significance, or more commonly no profile at all. The extraction method is the first step involved in DNA analysis, and is open to variation in DNA yield depending on the method used. It is an important step for the isolation and purification of DNA as it aims to remove inhibitors permitting downstream processes to work effectively. This process typically involves several wash steps and tube changes, each allowing for DNA retention to tubes and pipette tips, resulting in the loss of information. We report on the retention and loss of DNA using three commonly used extraction methods in forensic analysis. DNA concentrations were measured prior and post extraction using the QUBIT® fluorometer, and compared to assess the percentage lost.

DNA Extraction Methods Investigated

QIAamp Micro | Chelex | Promega IQ

Methods

- **Extraction:** Three common extraction methods were tested to determine the average loss of DNA from each: **QIAamp DNA Micro Kit** (QIAGEN), **DNA IQ™** System (Promega) and **Chelex**.
- Previously extracted DNA (from buccal swabs using QIAGEN Micro Kit) was quantified on a Qubit® 2.0 Fluorometer (Invitrogen™) and used as the control in this experiment. Control DNA ranging from 35 – 39 ng was used as the starting concentration for each extraction. Extractions were performed following the manufacturer's instructions for each kit and were eluted in a final volume of 30 □L for the DNA micro kit and 100 □L for Promega IQ and chelex.
- Chelex extraction involved adding 200 □L of 5 % chelex to the DNA in a 1.5 mL tube and incubating at 56 ℃ for 20 mins with shaking, followed by 100 ℃ for 8 mins with shaking. Sample was centrifuged at max speed (13000 g) for 3 mins. Liquid was removed without disturbing the chelex pellet and transferred into a new sterile 1.5 mL tube.
- Extractions were repeated eight times for each method used. Each extraction sample was quantified on the Qubit® following manufacturer's instructions, using 10 □L from each sample for quantification. The quantification results were compared against the initial input DNA to determine percentage lost.

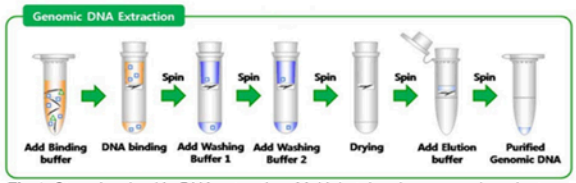

Fig 1. Steps involved in DNA extraction. Multiple tube changes and wash steps can contribute to exogenous DNA contamination as well as DNA loss. The extraction process is beneficial in removing inhibitors of downstream processes.

Image from Bioneer http://eng.bioneer.com

Results

DNA loss ranged from 36.5 % to 96.9 % across all methods, with QIAamp performing the best with the lowest average of 53.4 % DNA loss. Promega IQ and chelex were highly consistent with the results obtained, showing approximately 3 % variation between the highest and lowest losses observed. Although the results varied quite significantly for the QIAamp Micro kit, it still out performed the other kits with the highest DNA loss obtained (82.6 %) being less than the lowest percentages observed for the other two kits (89 and 94.3 %).

Table 1. Comparison of standard extraction methods, showing the range of DNA lost and kit efficiency across three methods.

DNA Extraction kit	Starting Mass (ng)	Average Final Mass (ng)	Average Percentage Lost (%)	Lowest/Highest Percentage Observed (%)
Promega IQ	36	1.5	95.8	94.3 / 96.9
QIAamp Micro	39	17.1	53.4	36.5 / 82.6
Chelex	35	3	91.5	89.0 / 92.3

Concluding Remarks

- Three common methods of DNA extraction are very inefficient with average loss ranging from 53.4 – 95.8 %
- DNA extraction is not ideal for trace evidence samples where minimal initial DNA is present
- Methods should be adjusted for trace evidence samples to reduce time and money wasted and improve results
- QIAamp Micro kit performed the best overall

Title: The development and implementation of direct PCR in casework

R. Ottens[1], J. Templeton[1], D. Taylor[2], D. Abarno[2], O. Handt[2], A. Linacre[1]

[1] *School of Biological Sciences, Flinders University, Adelaide, South Australia, Australia*

[2] *Forensic Science SA, Adelaide, South Australia, Australia*

DNA isolation and purification procedures are standard practice in the initial steps of DNA profiling when examining swabs, adhesive tapes and sections of fabric. Significant loss of DNA occurs during this process resulting in no DNA profile generated. Direct PCR circumvents the extraction process such that a DNA profile may be generated directly from the substrate. This potentially saves time, increases the sensitivity, reduces tube changes, and minimises steps open to error or contamination in the laboratory.

We report on the generation of DNA profiles from a range of substrates such as hairs, fibres, and swabs taken from touch substrates. Sections of hair shafts were placed in the reaction solution with no prior treatment. Fibres from clothing were treated likewise. Individual fibres from swabs used to remove latent DNA on plastics and metals were removed and placed directly in the reaction tube. The number of amplification cycles remained as recommended by the supplier.

The only alteration required to generate DNA profiles that can be uploaded to the Australian National Criminal Investigation DNA Database (NCIDD) was to increase the amount of DNA polymerase. The result is that DNA profiles can be generated from single hair shafts, single fibres and substrates touched for 5 seconds.

Introduction

Direct PCR in forensic science has the advantage of using all genetic material available from a sample as none is lost during the extraction process, saving time, money and increasing the magnitude of profiles obtained from trace evidence. Quantification of the DNA however, is not possible as all genetic material is used in direct amplification. A potential criticism of this method is that there is no knowledge of the amount of DNA in the tested sample. We report on an accurate method to quantify the DNA template used in direct PCR amplifications for the first time. The resulting magnitude of the alleles generated (relative fluorescence units or RFU value) can be used to calculate the original mass of DNA template.

Method

- **Amplification:** DNA was amplified using the NGM SElect™ kit (Life Technologies, Victoria, Australia) using a known mass of starting DNA template of 0, 0.05, 0.1, 0.2, 0.5 and 1 ng of DNA (2800M, Promega, Victoria, Australia). Each series of known mass of DNA (0 – 1 ng) was prepared three times for a total of 18 samples. Each sample was prepared in a 0.2 mL thin walled tube containing 25 □L of reagents following the manufacturer's instructions. A total of 29 PCR cycles was performed on a GeneAmp® 9700 96-well thermal cycler (Life Technologies) following manufacturer's instructions. PCR products (1 µL) were combined with 0.5 µL Liz 500™ (Life Technologies) separated using a 3130*xl* Genetic Analyser (Life Technologies). The data were analysed using GeneMapper□ ID v3.2 (Life Technologies) with a threshold of 50 RFU for allele assignment. Samples were run in triplicate on the 3130*xl* for a total data set of 54 profiles (nine data series of 0 – 1 ng).

- **DNA Analysis:** NGM SElect™ amplified 17 STR loci resulting in a possible 34 alleles. The average RFU value was calculated for each profile by dividing the sum of all RFU values of that profile, by the number of alleles obtained, counting a single allele for a homozygous locus. This average was recorded against the known DNA mass of the samples. Confidence intervals of 95 % were calculated by multiplying or dividing the expected DNA mass by 1.57

- **Reverse Quantification Analysis:** For each electrophoresis run, a calibration curve was produced using the positive control (0.5 ng) as the known upper standard and forcing the linear regression through the point of origin (making the assumption that no DNA will lead to no fluorescence). The average RFU of each sample on that run was then converted to an initial DNA mass using the calibration curve. This process was carried out on the DNA profiles generated from the prepared DNA dilution series (0 – 1 ng), to determine the accuracy of the reverse-quantification method.

Results

The reverse quantification method relies on the assumption that a linear relationship exists between template DNA mass and the fluorescence of the resulting DNA profile. This assumption was tested using the DNA dilution series (0 – 1 ng).

The 0.5 ng standard was used to generate the calibration curves and produced more evenly spread data around the expected value. The linear correlation of DNA mass and RFU value was determined using the coefficient of determination (R^2 value), for each series. The R^2 values ranged from 94.5 % to 99.9 %, with an average correlation of 97.6 % across all nine series (Table 1).

The estimated mass values obtained using the reverse quantification method can be seen in Figure 1. The log base 10 of the ratio of observed to expected mass values was modelled with a normal distribution that had a mean of 0 and a standard deviation of 0.1. This lead to 95% confidence intervals being calculated for expected mass being determined by a factor of 1.57 so that the intervals in Figure 1 were obtained by multiplying or dividing the expected DNA mass by 1.57. The 95% bounds covered 94% of observed data.

Results

Table 1: Calculated DNA mass (ng) for each series versus the actual DNA mass (ng) with corresponding R^2 values. Note the 0.5ng value is omitted as it was used to create the calibration curve for each series of data.

	Calculated DNA Mass (ng)								
Actual DNA Mass (ng)	*Series 1*	*Series 2*	*Series 3*	*Series 4*	*Series 5*	*Series 6*	*Series 7*	*Series 8*	*Series 9*
1.0	1.37	1.2	1.2	0.64	0.69	0.88	0.74	0.69	0.67
0.2	0.27	0.22	0.23	0.31	0.29	0.32	0.17	0.20	0.20
0.1	0.16	0.14	0.14	0.13	0.12	0.15	0.10	0.11	0.10
0.05	0.07	0.05	0.05	0.06	0.05	0.06	0.07	0.06	0.06
R^2 Value	**0.976**	**0.990**	**0.989**	**0.945**	**0.963**	**0.934**	**0.993**	**0.999**	**0.999**

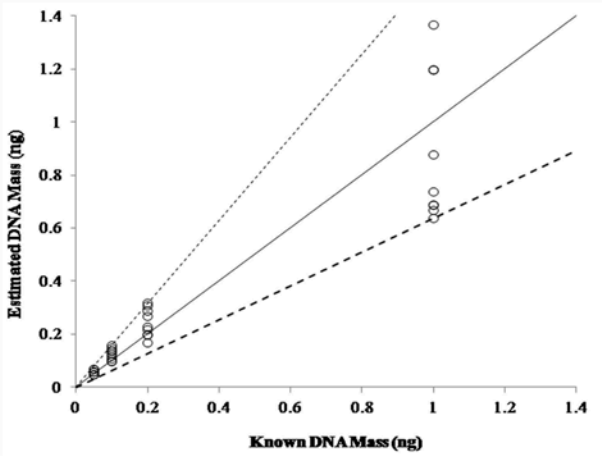

Figure 1: The known DNA mass compared to the estimated mass using the reverse quantification method (raw data seen in Table 1). The solid line represents the space where observed and expected values are equal and the dotted lines show the 95 % confidence interval boundaries on DNA mass prediction.

Concluding Remarks

- Previously there has been no means of estimating the initial amount of DNA used in a direct PCR.
- The statistical method described in this study enables the calculation of the DNA mass.
- The data indicate a high correlation between DNA mass and average RFU value, allowing for DNA mass calculations to be made within a factor of 1.57 of the actual value at a 95% confidence level.
- Can provide knowledge of amount of DNA template in direct PCR sample.
- Can help identify how much DNA was within a substrate prior to the amplification.
- Application beneficial in processing touch and trace DNA such as fingermarks and surface swabs as this technique is provides an informative estimation of DNA amount, even at low levels of starting DNA.
- As the standards required to calculate the DNA mass of samples are equivalent to the positive and negative control samples of a PCR setup, no additional laboratory work is required to implement this technique.

Direct PCR in forensic science has the advantage of using all genetic material available from a sample as none is lost during the extraction process, saving time, money and increasing the magnitude of profiles obtained from trace evidence. Quantification of the DNA however, is not possible as all genetic material is used in direct amplification. A potential criticism of this method is that there is no knowledge of the amount of DNA in the tested sample. We report on an accurate method to quantify the DNA template used in direct PCR amplifications for the first time. The resulting magnitude of the alleles generated (relative fluorescence units or RFU value) can be used to calculate the original mass of DNA template. A number of standards of known DNA quantity were amplified using the NGM SElect™ STR kit, and were separated on a 3130*xl*. The data was plotted on a graph to assess linearity, and therefore calculate mass based on the RFU value. The data indicated that the original template DNA could be calculated within ± 64 pg of the known DNA mass. This method can be used to report the estimated number of cells from a sample processed via direct PCR.

ABSTRACT

We report on a novel direct PCR approach for retrieving touch DNA from handled items. Trace levels of DNA on handled items can be difficult to recover and analyse using standard methodology. The lack of a full nuclear STR DNA profile may be related to insufficient DNA being present initially, the presence of PCR inhibitors, or the loss of nucleic acid during sample collection and processing. The aim of this study was to optimise the swabbing method used to collect DNA and to improve the success rate of STR-based DNA profiling from touched items. A comparison was carried out to evaluate the use of three common swab types, nylon, cotton and foam at retrieving and releasing template DNA for amplification by direct PCR. To test the effectiveness of our method at processing low levels of DNA, complete STR DNA profiles were obtained from fingerprints deposited onto sterile plastic slides, which were swabbed and subjected to direct PCR. Our findings indicate the potential use of direct PCR when analysing samples that contain limited DNA.

1. Introduction

Low levels of DNA recovered from touched items can be close to the limit of detection for current STR-based DNA profiling kits. The success of a DNA profile depends largely on how much DNA is retrieved from the evidence. Cotton swabs, pre-moistened with distilled water, are used routinely in forensic laboratories. However, other swab types should also be considered due to the low success rate of current methods. Following DNA collection, current methodology subjects the swab to a DNA extraction to isolate and purify the target DNA, typically using a solid phase substrate, prior to amplification. The DNA extraction process contributes to a significant loss (20–70%) of sample DNA [1] and has the potential to introduce extraneous DNA into the reaction [2]. Direct PCR circumvents the need for a DNA extraction. For direct PCR, the biological material is transferred directly into the PCR tube with no prior extraction or purification steps. Previous studies report full STR DNA profiles obtained from trace evidence using direct PCR [3,4]. The aim of this study was to examine aspects of sample collection, apply the method of direct PCR to low level DNA templates, and to improve the success of STR DNA profiling. In this study we report the ability of direct PCR, using 29 cycles, to generate full STR DNA profiles from fingerprints deposited on plastic substrates.

2. Materials and methods

Control DNA (2800 M, Promega) of a known concentration (1 ng/μL) was deposited onto 3× sterile plastic microscope slides and swabbed using either foam (Whatman, USA), DNA-free nylon FLOQswabs™ (Copan Industries, Vic) or cotton swabs (Livingstone, NSW). For direct PCR, a 2 mm^2 portion of each swab tip was cut using a sterile scalpel blade and placed directly into a 0.2 mL PCR tube. Amplification conditions followed the Profiler Plus® STR kit (ABI) guidelines in a final 25 μL reaction volume and standard 28 cycles. For fingerprint deposition, three donors placed the index finger of their dominant hand onto a sterile plastic slide 2 h after hand washing. For direct PCR, a 2 mm^2 portion of the swab tip was cut using a sterile scalpel blade and placed directly into a 0.2 mL PCR tube. Amplification followed the NGM™ STR kit (ABI) guidelines in a final 25 μL reaction volume and 29 cycles. PCR products were run on the 3130*xl* (ABI) and profiles analysed using GeneMapper™ ID v3.2 software and a peak amplitude threshold of 30 RFU was used to assign alleles.

3. Results and discussion

Nylon swabs generated the highest DNA yield, as assayed by the relative fluorescence units (RFU) of peak heights, followed by foam and then cotton swabs (Fig. 1). Full STR DNA profiles were

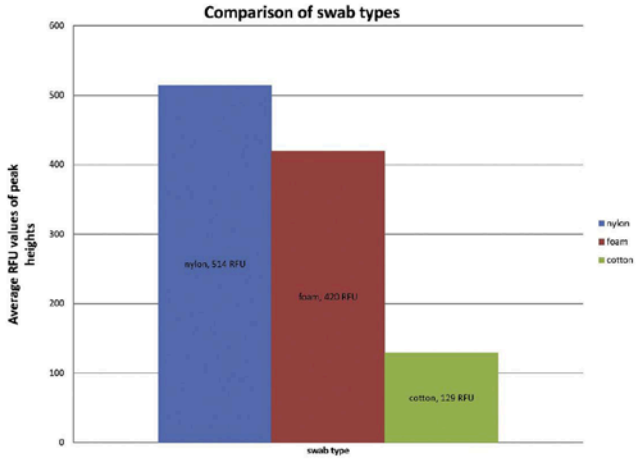

Fig. 1. A comparison between swab types, using control DNA deposited on a plastic slide, prior to swabbing, PCR and STR DNA profiling.

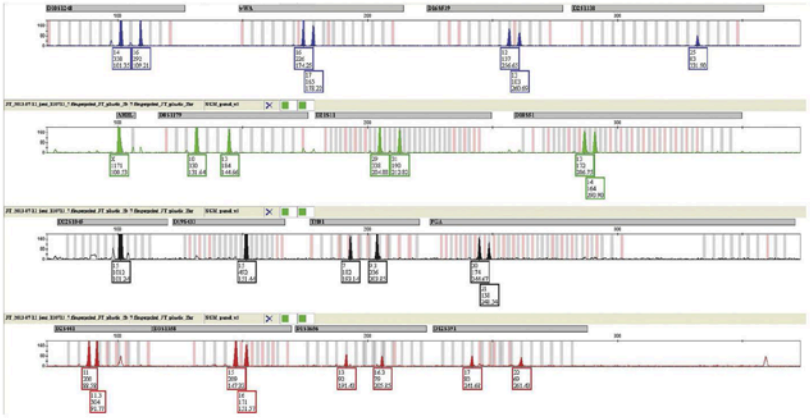

Fig. 2. Example of an STR DNA profile generated, using direct PCR, from a fingerprint deposited on a plastic slide prior to swabbing and processing (29 cycles of PCR, using NGM™ STR kit (ABI)).

obtained, using nylon flocked swabs and direct PCR, from all three fingerprints deposited on plastic substrates 2 h after the donor washed their hands. No allele drop-in or allele drop-out was observed (Fig. 2). Laboratories may benefit from using direct PCR on handled items due to its high-throughput potential and increased sensitivity. However, the success and quality of DNA profiles obtained using direct PCR will be dependent on the nature of the material examined and the presence of PCR inhibitors; which are generally eliminated during the extraction process.

4. Conclusion

Nylon flocked swabs (Copan) provided the optimum method of DNA recovery from plastic slides. Nylon flocked swabs and direct PCR was used to generate full STR DNA profiles from three fingerprints deposited on plastic substrates 2 h after the donor washed their hands. No allelic drop-in was detected and only 29 cycles were used in the PCR process. The method of direct PCR should be considered as an alternative method for analysing samples that contain low amounts of DNA for use in a high-throughput environment. A validated study is required to assess the limitations of the direct PCR approach. However, we anticipate the method to have future niche applications in analysing latent DNA recovered from touched items that face the limits of detection when using standard protocols.

Direct PCR from Human Hair

3.1 Preface

Single human hairs may be encountered in a forensic investigation in one of three growth stages: anagen hairs are in the active growth phase and maintain a follicular tag or skin sheathing at the root end, to be found loose would suggest forceful removal; telogen hairs have completed the growth cycle, shedding themselves naturally once skin sheathing at the root end has finished degrading; catagen hairs represent the transitional growth phase between the active (anagen) and dormant (telogen) growth phases. DNA is intrinsic to the hair, associated higher with the active growth phase where skin cells and sheathing material are still present, and is hypothesised that cell-free DNA is present on the shaft of the hair. Human hair represents an on going challenge in forensic casework due to the low amounts of DNA associated with a single hair and are notoriously difficult to consistently obtain DNA information from, if at all [1-5]. This is particularly true for telogen hairs that lack sheathing material, and as they shed naturally they are more commonly found in a forensic investigation [5-7]. Although a shift from standard STR typing to mini-STR nuclear DNA analysis has improved the chances of obtaining alleles from single hairs [4, 8-10], improvised pre-treatment methods of hairs such as multiple wash steps, certain staining techniques and extraction methods have failed to make a significant difference in success rates [7, 11, 12].

Human hairs are an ideal substrate for direct PCR as inhibitors, such as humic acid (found in soil) or haem (found in blood), are unlikely to be found on the surface of the hair. Melanin (a PCR inhibitor found within the hair) is unlikely to be released or broken down during the amplification stage as the hairs are not digested during this process, the hairs remain intact. The following sections investigate the application of human hairs as a substrate for direct PCR (*3.2*), the optimisation of the substrate (*3.3*), and further testing and implementation of the technique with human hairs (*3.4*).

TECHNICAL REPORT

Successful direct amplification of nuclear markers from a single hair follicle

Renée Ottens · Duncan Taylor · Damien Abarno · Adrian Linacre

Accepted: 15 December 2012 / Published online: 30 December 2012

Abstract We report on successful amplification of DNA profiles from a single hair. Direct amplification was used on the root tip of both anagen and telogen hairs using a kit to amplify 15 STR loci. All 30 anagen hairs tested from five different people gave full DNA profiles after 29 cycles with no allelic drop-in or heterozygous imbalance. Six of the 30 telogen hairs tested resulted in a full DNA profile, and a further four telogen hair samples tested produced a DNA profile of five or more complete loci that could be uploaded to the National DNA Database (Australia). A full DNA profile was also obtained from the shaft of an anagen hair. Current practice for many laboratories is that a single hair may not be subjected to DNA testing as there is little chance of success, hence this 100 % success rate from anagen hairs is a significant advancement. A full DNA profile was obtained from a 5 year-old single hair illustrating the success when using direct PCR rather than attempting an extraction prior to the amplification step. The process described deliberately uses current DNA profiling methods with no increase in cycle number, such that the methodology can be incorporated readily into operational practice. For the first time in the field of human identification, single hairs can be analyzed with confidence that a meaningful DNA profile will be generated and the data accepted by the criminal justice system.

Introduction

Direct PCR of samples has gained much interest in a forensic context due to the potential saving in time [1–4], increase in sensitivity, and minimizing of steps open to error or contamination [5]. Much of the focus has been on direct amplification from a stain [6] with an emphasis also on the speed of the DNA typing [7] and the types of DNA polymerase used. A previous report illustrated the potential benefit of direct amplification from fibers [5] and touch DNA [8]. To date there has been no testing of human hairs with direct PCR despite the prevalence of hair sampling during forensic examination [9]. The potential to generate a profile from hair follicles is dependent on the presence of nucleated cells such as within a follicular tag, as such hairs in the growth phase (anagen) being more likely to generate a result than hairs in the dormant phase (telogen). In many forensic laboratories, nuclear DNA profiling is not attempted on hairs when there is no indication of a root sheath at the proximal tip; leading to a potential loss of information. Mitochondrial DNA testing is possible from single hairs for animal testing [10] and human identification [11–13] but requires specialist equipment and skills. If nuclear DNA testing is required then there may be a need to use low template DNA typing methods [14]. Trace amounts of nuclear DNA limit the possibility of generating meaningful DNA profiles from single hairs or hairs in the telogen state. Current practice at Forensic Science South Australia (FSSA) is that hairs are examined by microscopy for the presence of sheath material. If there is no sheath material the hair is not submitted for DNA analysis as there is a low probability of obtaining an interpretable DNA profile. While the majority of hairs on the scalp are in the anagen phase, it is telogen hairs that are found more frequently in forensic investigations as these are the hairs that

are shed naturally, thus the ability to obtain nuclear DNA profiles from these samples would be of great benefit.

We report on the first use of direct amplification of a DNA from single hair in the anagen and telogen growth phases. As a single hair is used in the analysis it is assumed that any resulting DNA profile will be from a single source. The aim was to develop a simple, operational method that could be used routinely in forensic science casework with no further modification and a greater DNA profiling success rate than standard extraction methods on this type of sample. For ease of implementation, the process should also adhere to standard methods with no increase in the cycle number and also generate DNA profiles from hairs of unknown age.

Materials and methods

Samples

A buccal swab and scalp hairs were collected from both male and female donors working at FSSA. DNA was extracted from the buccal swabs using the QIAGEN (Doncaster, Victoria, Australia) Mini DNA extraction kit following the manufacturer's protocol. The resulting DNA profiles were used in subsequent comparisons.

Donors were asked to pluck a number of hairs from their scalp; as well as collect loosely/naturally shed hairs. Each hair was examined microscopically to determine its growth phase. Hairs were categorized as either anagen or telogen (with one example of catagen). A total of 30 hairs in the anagen growth phase and also 30 hairs in the telogen growth phase were analyzed. Two examples of body limb, pubic, and eyebrow hair samples (six in total), that had been stored in sealed plastic bags and kept at room temperature since 2007, were also supplied by FSSA. The shaft of three anagen hairs from one individual was also analyzed.

Direct PCR amplification and conditions

Direct PCR was conducted by removing approximately 5 mm of the proximal tip using sterile scissors and tweezers. For the shaft samples, once the proximal tip had been cut for use, the next 5 mm was cut for use. The hair fragment was placed into a 0.2 mL thin walled tube containing 10 μL of PCR master mix from either the AmpFℓSTR® NGM™ or NGM SElect™ kit (Life Technologies, Victoria, Australia) along with 5 μL of the primer mix and 1 μL of AmpliTaq Gold® DNA polymerase. A further 9 μL of sterile H_2O were added to make the final volume 25 μL. The amplification was conducted in a GeneAmp® System 9600 thermal cycler (Life Technologies) using the manufacturer's recommended conditions. The standard 29 cycles was used for all reactions. There was no alteration to the methodology of amplification deliberately so as to ensure that the process could be adopted readily by the forensic science community. The NGM™ and NGM Select™ kits amplify 15 STR loci plus the amelogenin locus.

Capillary electrophoresis

Capillary electrophoresis was performed on an ABI 3130*xl* Genetic Analyser (Life Technologies) using POP-4™ polymer (Applied Biosystems). An aliquot of either 1 μL or 1 μL of a 1 in 50 dilution into H_2O of the PCR sample was added to a solution of 0.5 μL of ABI GeneScan-600 LIZ® Size Standard and 9.5 μL of Hi-Di™ Formamide. Samples were then denatured at 95 °C for 3 min. Electrophoresis was conducted at 3 kV with a 10 s injection. The data were analyzed using Genemapper® v3.2. The detection threshold was set at 50 relative fluorescence units (RFU).

Data analysis

The data were tabulated based on the number and percentage of alleles generated from the 15 STR loci amplified by the NGM™ and NGM SElect™ kits. Currently FSSA use Profiler Plus (Life Technologies), which amplifies 9 STR loci plus amelogenin. Five complete STR loci are required to up-load to the Australian National DNA Database, therefore a profile that can be uploaded if there are greater than five complete loci whereas an incomplete profile is when less than five loci are generated.

Results and discussion

Anagen and catagen hairs

A total of 30 hairs (29 anagen and 1 catagen) from five individuals were amplified directly using the NGM™ and NGM SElect™ kits and the data analyzed. A full profile, comprising all 15 STR loci and the amelogenin locus, was obtained for every individual hair sample (Fig. 1). In 30 instances, the DNA profile generated from the anagen hair section matched the DNA profile of the donor with no additional alleles and no allelic drop-out. Initially, most of the samples yielded DNA profiles with RFU values above 10,000 for some loci; this is typical of over amplification. We recommend a dilution of the final PCR product for anagen hair samples. For example, a 1 in 50 dilution of the anagen samples decreased the average RFUs from 4,217 to 1,240 (Table 1). Allele pull-up was not observed in the

diluted samples, and background noise was also greatly decreased. The average heterozygous peak balance (defined as the lower intensity peak divided by the higher intensity peak) was observed to be 84.8 % for neat samples and 86.6 % for diluted samples. There was no increase in stochastic effects compared to DNA profiles generated using the standard extraction methods. Heterozygous balance was good (with the two peak heights being within 80 % of each other in all direct amplification experiments) and dropout occurred in the expected range.

Telogen hairs

A total of 30 telogen hairs from five individuals were amplified directly and the data analyzed. Full DNA profiles were obtained from six samples (Fig. 2), and up-loadable profiles (with five or more complete loci) were observed in a further four samples. The remaining twenty samples yielded profiles containing eleven alleles or less. In all 30 instances, the DNA profile generated from the telogen hair section matched the DNA profile of the donor with no additional alleles. In total, the 30 samples had an average RFU value of 1,202 and heterozygous peak balance of 82.4 %.

Aged hairs

Two hairs of different somatic origin (pubic, eyebrow, and body limb) were amplified directly using the NGM™ kit and the data analyzed. The growth stages of the hairs were not identified prior to amplification to avoid the risk of transferring and losing any DNA onto the microscope slides. The hairs had been stored in sealed plastic bags for use in microscopic hair training without taking measures to preserve the DNA at the root. As the objective was to establish if any meaningful DNA profiles could be obtained via direct PCR, a comparison to a reference profile was not required. The complete 15 STR loci were observed for each of the six samples and the two samples from each hair type revealed identical profiles as each other. In total the six samples had an average RFU value of 2,929 and heterozygous peak balance of 82.9 %.

Anagen hair shaft

Standard procedure at FSSA for anagen hair extraction includes using a section of the hair shaft as the negative control. The first 5 mm from the proximal tip is removed

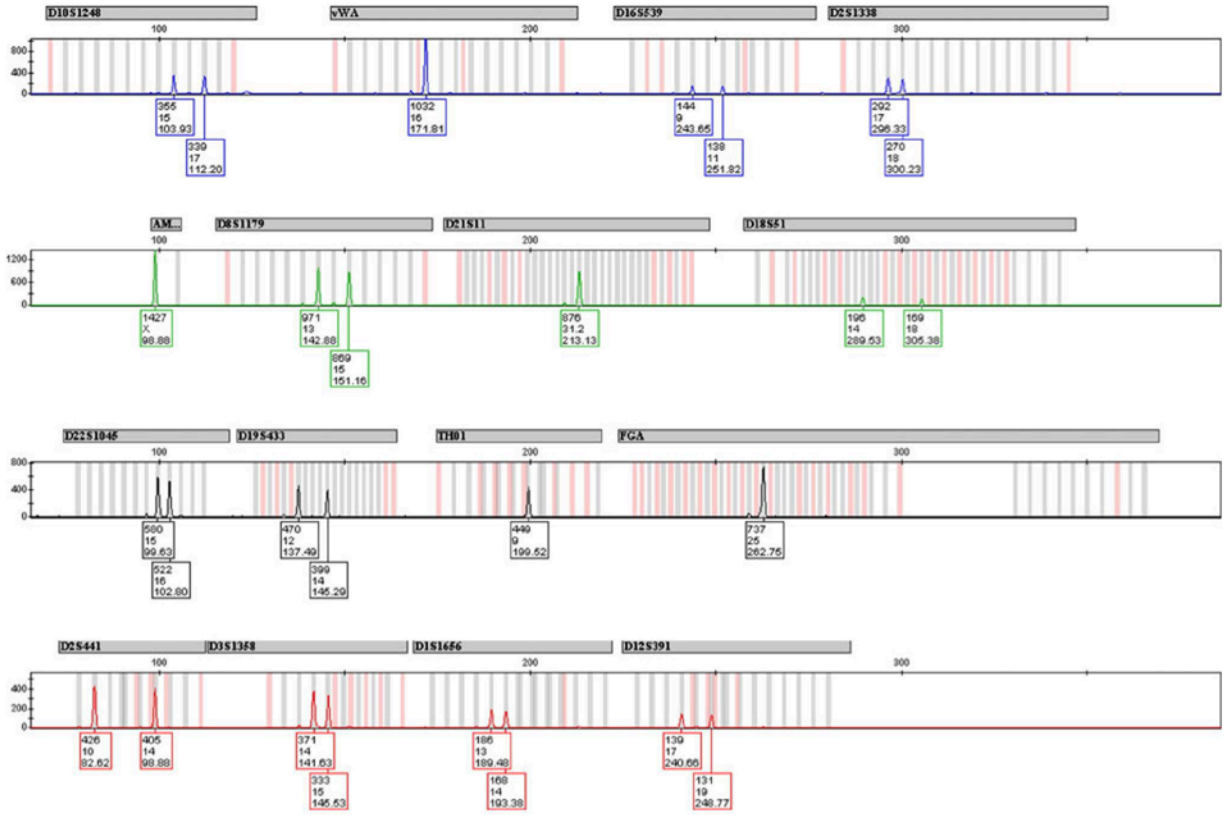

Fig. 1 Chromatogram of nuclear DNA from a single anagen hair root, amplified using AmpFℓSTR® NGM™ kit at 29 cycles on a GeneAmp® System 9600 thermal cycler. Sample was injected on an Applied Biosystems 3130*xl* Genetic Analyser at 3 kV for 10 s

Table 1 Comparison of DNA profiles obtained from different growth phases of hair, showing the success rate (out of 30 STR alleles for NGM and 18 STR alleles for Profiler Plus)

Hair type	NGM profile type (%)			Average RFU
	Complete	Incomplete and up-loadable	Incomplete and not up-loadable	
Anagen	100	0	0	4,217 (1,240 diluted)
Telogen	20	13.3	66.7	1,202
Aged	100	0	0	2,929

Hair type	Profiler plus profile type (%)		
	Complete	Incomplete but up-loadable	Incomplete and not up-loadable
Anagen	53	12.5	34.5
Telogen	10	6	84

An incomplete and up-loadable profile is when less than all the alleles, but more than 5 complete loci, were generated. The average RFU values for hairs tested using direct PCR are also shown

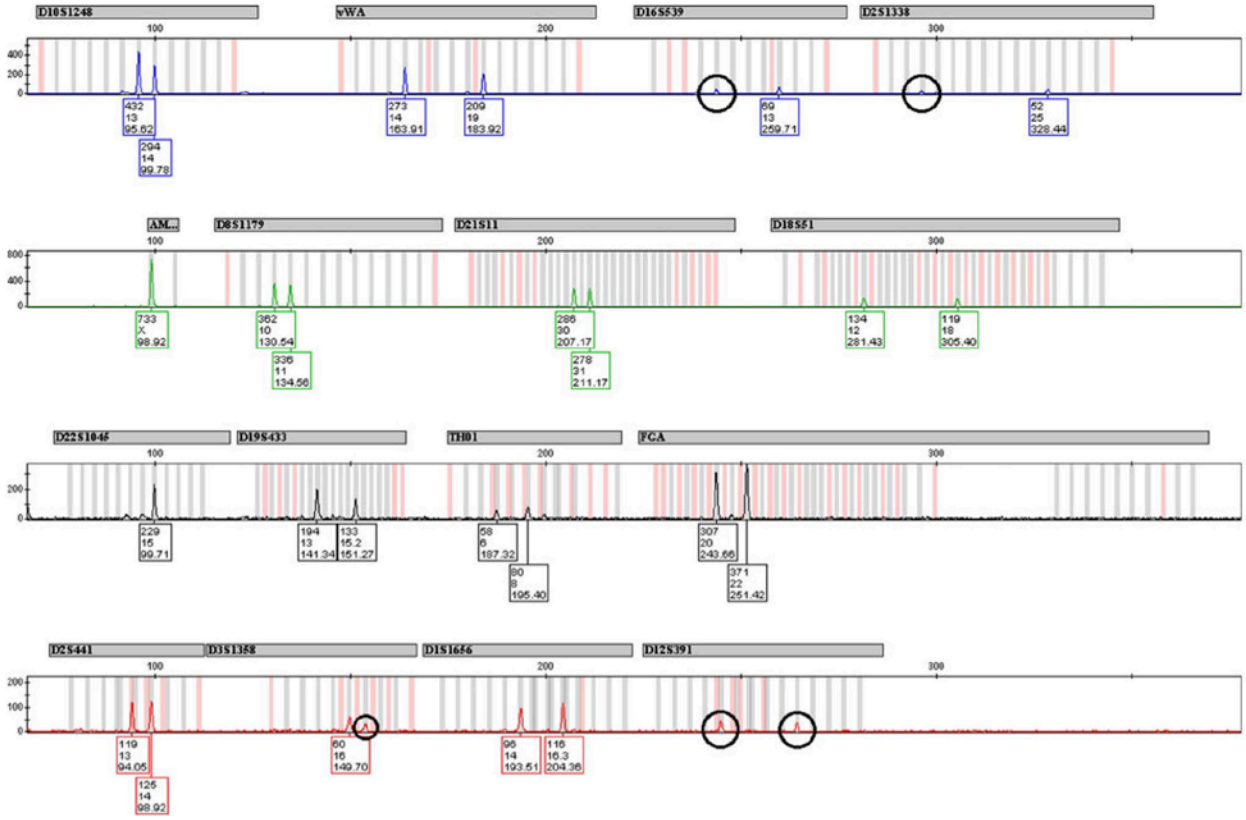

Fig. 2 Chromatogram of nuclear DNA from a single telogen hair root, amplified using AmpF*ℓ*STR® NGM™ kit at 29 cycles on a GeneAmp® System 9600 thermal cycler. Sample was injected on an Applied Biosystems 3130*xl* Genetic Analyser at 3 kV for 10 s. Allelic drop out can be observed at the *circled* loci D16S539, D2S1338, D3S1358, and D12S391

for extraction, and the following 5 mm is used as the negative control. This method was adapted using direct PCR for three anagen hair shaft samples. A full profile belonging to the individual was obtained from one hair sample. The remaining two shaft samples yielded eight alleles each.

FSSA comparison

FSSA have previously conducted an in-house study to compare the growth phase of a hair sample against the DNA profile obtained in order to determine which category of hair yields the most complete DNA profile. The hair type and percentage of profile obtained can be observed in Table 1. A profile of value (up-loadable to the National DNA Database, Australia) was obtained in 33.3 % of telogen samples in this study compared to 16 % by FSSA. Similarly, the success for obtaining meaningful profiles from anagen samples has increased from 65.5 to 100 % in this study. However, telogen hairs in forensic practice are typically not processed for DNA due to the low success rate. For example, based on the FSSA standard operating procedure for hair analysis, a telogen hair would not be submitted for further DNA analysis. There is no standard operating procedure nationwide for hair analysis; however there are numerous studies detailing the analysis on single telogen hairs for forensic purposes resulting in limited success and inconsistent results [9, 15].

Conclusion

We demonstrated a 100 % success rate for the generation of complete profiles (15 STR loci and amelogenin) from a single hair in the anagen growth phase. This is a significant increase compared to the process of performing standard DNA extraction then amplification of the extract. It is noted that some of the differences between the results from the standard extraction (using Profiler Plus) and the direct amplification (using NGM) could be attributed to improvements in the kit chemistry, although the commercial amplification kit used in the direct amplification is not designed primarily for this application.

A complete DNA profile at all fifteen STR loci were also obtained from hairs that have been stored for 5 years. It was found that direct PCR of single anagen hairs produced overloaded DNA profiles after the standard 29 amplification cycles and we recommend a dilution of the product prior to electrophoresis of the sample. The heterozygote balance was typically greater than 80 % and in no case was below 60 %. The profiles indicated no stochastic effects beyond what is expected from standard DNA profiling techniques. No allelic drop-in or any indication of contamination was noted in any of the 66 samples tested.

Direct PCR produced DNA profiles that could be uploaded to the National DNA Database (Australia) from a single hair in the telogen growth phase in ten of the 30 samples tested. Twelve telogen hairs produced partial profiles with eleven alleles or less, and the remaining eight samples produced no alleles. In all cases the profiles obtained were more complete and of greater quality than profiles obtained using standard extraction methods.

The generation of DNA profiles from telogen hairs was not always dependent on initial visualization of a follicular sheath. It may be that free-DNA on the surface of the hair, or associated loosely with the hair shaft, is that source of the DNA. Free-DNA has been suggested as a source of DNA from a variety of sources previously such as fabrics [5] and sweat [16].

There is the possibility of detecting a DNA profile from a hair that is not from the donor of the hair. The introduction of non-donor DNA to a hair can occur prior to the hair being examined in the laboratory and secondly during the laboratory process. The first is due to extraneous DNA from another individual being deposited on the hair while the second can be more formally referred to as contamination of the hair during laboratory procedures.

The deposition of a second individual's DNA onto a hair could be determined readily if the resultant profile is from more than one individual. This indicates multiple donors to the hair and would readily be assessed by the analyst. The potential risk is that a single source profile is obtained, which has not originated from the DNA of the hair donor, and would not be flagged by an analyst. This type of result from a single hair is potentially possible, however as it is proposed that nuclear DNA on the surface of the hair is the predominant source of DNA, then a second contributor (i.e. not from the hair donor) is only possible if a source of DNA comes into contact with the hair surface and no profile is obtained from the donor of the hair. We believe this possibility to be unlikely. Alternatively this may result from the hair being contacted with a biological fluid such as semen or blood. Prior microscopic examination of a hair by a trained analyst would determine the presence of a biological fluid on the hair shaft or bulb.

We propose that contamination of a single hair during the laboratory process is less likely to occur from this direct approach compared to standard extraction procedures. Standard DNA extraction procedures involve numerous wash methods and tube changes, each being a possible step where contamination may occur before the amplification of the DNA. It is also these same steps where the initial DNA can be lost, either via washing or retained on the silica membrane. The method described in this paper avoids the extraction process and thus greatly reduces DNA loss and potential contamination prior to amplification.

This simple process of direct PCR from single hairs can be readily adopted for use into forensic DNA practice and we demonstrate that the process has the capability of generating full DNA profiles from anagen hairs, aged hairs, and partial profiles from single telogen hairs. Hairs that would otherwise not be tested, as there was little chance of gaining a meaningful profile, can now be profiled.

Key Points

1. A successful and novel method for obtaining DNA profiles from single hairs using direct PCR.
2. The DNA extraction process was completely circumvented. This allows for a greater yield of DNA from hair, as DNA is not lost via wash steps or tube changes.
3. Full profiles were obtained in 100 % of anagen hair samples. Profiles 'up-loadable' to the Australian National DNA Database were obtained in 33.3 % of the telogen hair samples.
4. Allelic drop-in or contamination was not observed in any of the 66 hair samples tested.
5. Standard protocol for DNA amplification from the NGM™ and NGM SElect™ STR typing kits was not modified, allowing for easy and quick implementation into forensic laboratories.
6. This method is cost-effective and time saving in forensic casework, as a lengthy extraction process is not required.

Acknowledgments Funding for Renée Ottens and Adrian Linacre was provided by the Department of Justice South Australia. We are grateful to Edmund Silenieks of FSSA for assistance with the microscopy and Julianne Henry also of FSSA for providing data on the success of STR typing of hairs.

ABSTRACT

Anagen hairs are in the active growth phase, and when forcefully removed, may contain an intact root or sheathing. The hair root or sheathing is a source of nucleic DNA and can be amplified using direct PCR. Human identification STR kits are optimised to a small range of input DNA for PCR. Anagen hairs are unable to be quantified prior to amplification and can exhibit characteristics of an over-loaded DNA sample when analysed. The aim of this study was to optimise direct PCR for anagen hair sampling. Two separate modifications to the downstream processes were carried out in order to determine the most effective method at minimising PCR artefacts. Decreasing the cycle number from the standard 29 cycles to 27 cycles when using the NGM™ kit displayed the best results for this method. However, decreasing the cycle number may increase allelic drop-out and would be costly for laboratories to perform an in-house validation. Diluting the PCR product during electrophoresis analysis minimises the effects of PCR artefacts in the same way decreasing the cycle number does. Diluting the PCR product is the most cost-effective method and does not increase the chance of allelic drop-out.

1. Introduction

Due to the nature of direct PCR, a sample is unable to be quantified prior to amplification. The extraction step is bypassed and therefore quantification is not possible. This increases the sensitivity of PCR, highlighting its benefit for latent DNA samples. However, the recommended input of template DNA for most human identification kits is between 0.5 and 2 ng [1]. A single anagen hair sample processed directly can sometimes produce chromatograms with characteristics of an overloaded PCR sample [2], suggesting that a single anagen hair contains greater than 2 ng of nucleic DNA. Characteristics of adding too much DNA include split peaks, uneven heterozygous peaks, and increased "stutter" and "pull-up" [3,4]. This study identifies two methods that can be applied in the downstream processes of direct PCR for the optimisation of anagen hair sampling that minimises the effects of PCR artefacts.

2. Materials and methods

2.1. Decreasing PCR cycle number

A total of 20 anagen hairs were used to assess any benefits associated with decreasing the PCR cycle number to 28 or 27. Amplification of the samples was performed on the GeneAmp® 9700 96-well thermal cycler (Applied Biosystems) following the AmpFℓSTR® NGM® kit (Applied Biosystems, USA) manufacturer's instructions. The cycle number was decreased from the standard 29 to either 28 or 27 cycles. Amplified PCR product (1 μL) was run with 9.5 μL Hi-Di™ Formamide (Life Technologies, Victoria, Australia) and 0.5 μL LIZ-600™ size standard (GeneScan™, Applied Biosystems, USA). Samples were injected on an Applied Biosystems 3130*xl* Genetic Analyser at 3 kV for 10 s. The data were analysed using GeneMapper® software v3.2.

2.2. PCR product dilution

A total of 30 anagen hairs were used for PCR product dilution. Amplification of the samples was performed on the GeneAmp® 9700 96-well thermal cycler following the AmpFℓSTR® NGM® kit manufacturer's instructions. Each amplified PCR product from a single anagen hair was diluted into concentrations of 1:10, 1:30 and 1:50, in which 1 μL from a dilution was combined with 9.5 μL Hi-Di™ Formamide and 0.5 μL LIZ-600™ size standard. Samples were injected on an Applied Biosystems 3130*xl* Genetic Analyser at 3 kV for 10 s. The data were analysed using GeneMapper® software v3.2.

3. Results and discussion

3.1. Decreasing PCR cycle number

Decreasing the cycle number to 27 cycles for the NGM® kit provided the best results in minimising PCR artefacts. Although

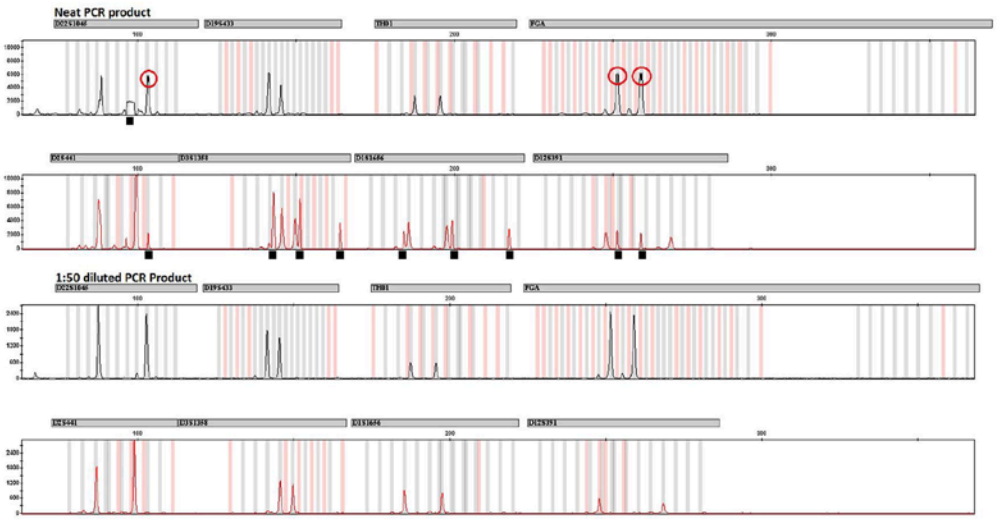

Fig. 1. Chromatogram of nuclear DNA from a single anagen hair root, amplified using AmpFℓSTR® NGM™ kit at 29 cycles on a GeneAmp® System 9600 thermal cycler. Figure shows 8 loci from NGM™ kit. PCR sample was analysed neat and diluted to a concentration of 1:50 before it was injected on an Applied Biosystems 3130*xl* Genetic Analyser at 3 kV for 10 s. Red circles indicate split peaks and black squares indicate pull-up in the neat sample. Split peaks and pull-up is not observed in the diluted sample.

100% success rate was maintained for obtaining a full profile from a single anagen hair, a decrease in cycle number has not been validated by the manufacturer and can be time consuming and expensive for a forensic laboratory to complete in-house.

As not every anagen hair contains the same amount of DNA, the decrease in cycle number could potentially decrease the success rate of obtaining a full DNA profile.

3.2. PCR product dilution

It was found that a dilution of 1:50 was the most efficient in reducing the effects of PCR artefacts without losing alleles to over-dilution (Fig. 1). It is recommended that several dilutions, including the original PCR product, are analysed on the same run to save time. There was a decrease of 29.4% in the average RFU when anagen hair samples were diluted to a 1:50 concentration.

4. Conclusion

Anagen hair samples when amplified using direct PCR methods can exhibit PCR artefacts that are consistent with overloading a PCR with too much DNA. Our recommendation is to use the lowest cycle number that has been validated by the STR kit in use, or to dilute the final PCR product to minimise the effects of pull-up, split peaks and stutter.

Role of funding

Funding was provided by the Department of Justice, South Australia.

Conflict of interest

None.

Acknowledgements

We thank members of Forensic Science South Australia and the School of Biological Sciences at Flinders University for assisting with reagents and providing helpful advice.

3.4 Applications

In February 2013, I travelled to the Life Technologies Training Laboratory in Melbourne (VIC, Australia) to investigate and compare anagen and telogen hair samples between two human identification kits: AmpFℓSTR® NGM SElect™ PCR amplification kit and the GlobalFiler™ Express PCR amplification kit (Life Technologies), with and without modified PCR amplification conditions (decreased cycle numbers, and additional AmpliTaq Gold® DNA polymerase). The GlobalFiler™ Express kit incorporates the use of a 3500*xL* Genetic Analyser (Life Technologies), which is required to analyse 6-dye data. GlobalFiler™ Express is an STR multiplex assay optimised to allow direct amplification from the following types of single-source samples:

- Blood and buccal samples on treated paper substrates without the need for sample purification.
- Blood and buccal samples collected on untreated paper substrates and treated with Prep-n-Go™ Buffer.
- Buccal samples collected on swab substrates and treated with Prep-n-Go™ Buffer.

The kit amplifies 21 autosomal STR loci, Amelogenin, one Y-STR locus, and one Y insertion/deletion (Y indel) locus in a single PCR (24 loci total).

A total of 72 hairs (36 anagen and 36 telogen) from six individuals were amplified directly using the NGM SElect™ and GlobalFiler™ Express kits. Approximately 5 mm of the proximal tip of each hair was removed and placed into a 0.2 mL thin walled tube containing the PCR buffer constituents for the respective kits. NGM SElect™ required 10 µL of PCR master mix, 5 µL of primer mix, and either 10 µL of Low-TE Buffer or 9 µL with 1 µL of AmpliTaq Gold®, making a total volume of 25 µL. GlobalFiler™ Express required 6 µL of PCR master mix, 6 µL of primer mix and either 3 µL of Low-TE Buffer or 2 µL with 1 µL of AmpliTaq Gold®, making a total volume of 15 µL. Amplification was conducted in a GeneAmp® System 9700 thermal cycler using the manufacturer's recommended conditions for each kit. The standard 29 cycles was used for all NGM SElect™ reactions, and 27, 28 or 29 cycles for GlobalFiler™ Express reactions.

Results indicated that without additional AmpliTaq Gold®, resulting DNA profiles displayed signs of high inhibition typical of over amplification and were unable to be analysed. Profiles presented with split-peaks or incomplete adenylation, imbalanced heterozygous peaks, imbalanced loci (complete locus drop out of larger fragments), and increased baseline noise (Figures 3.1 and 3.2).

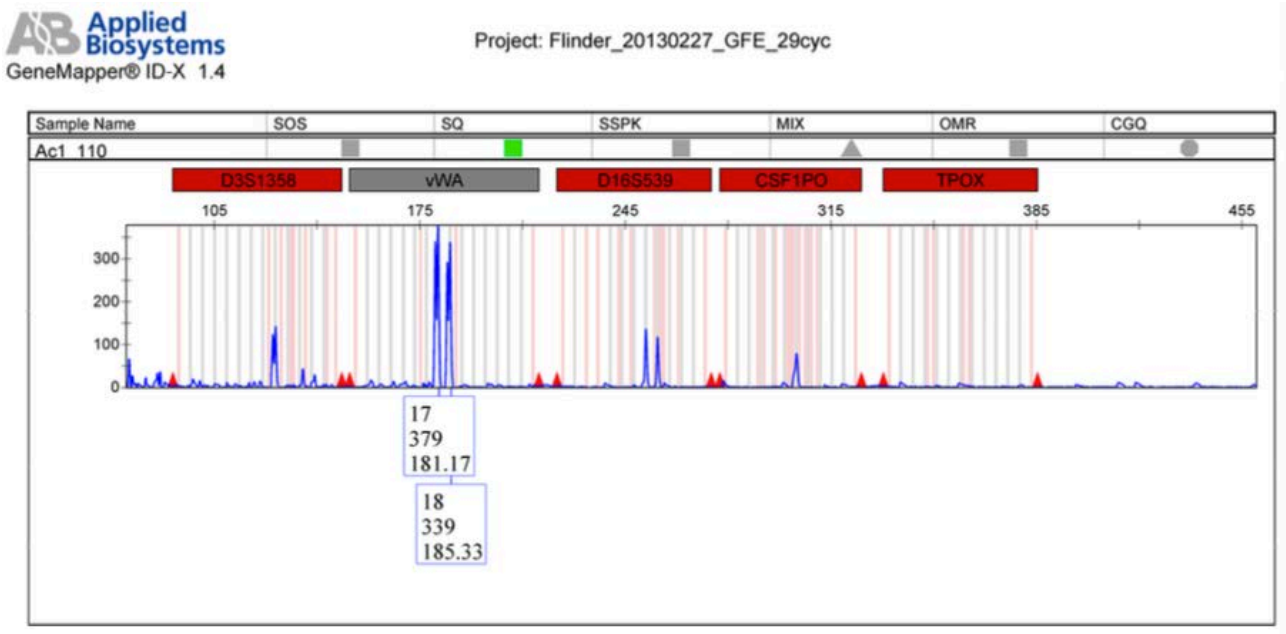

Figure 3.1 – Chromatogram of nuclear DNA from a single anagen hair root amplified using GlobalFiler™ Express PCR kit at 29 cycles on a GeneAmp® System 9700 thermal cycler, without additional AmpliTaq Gold®.

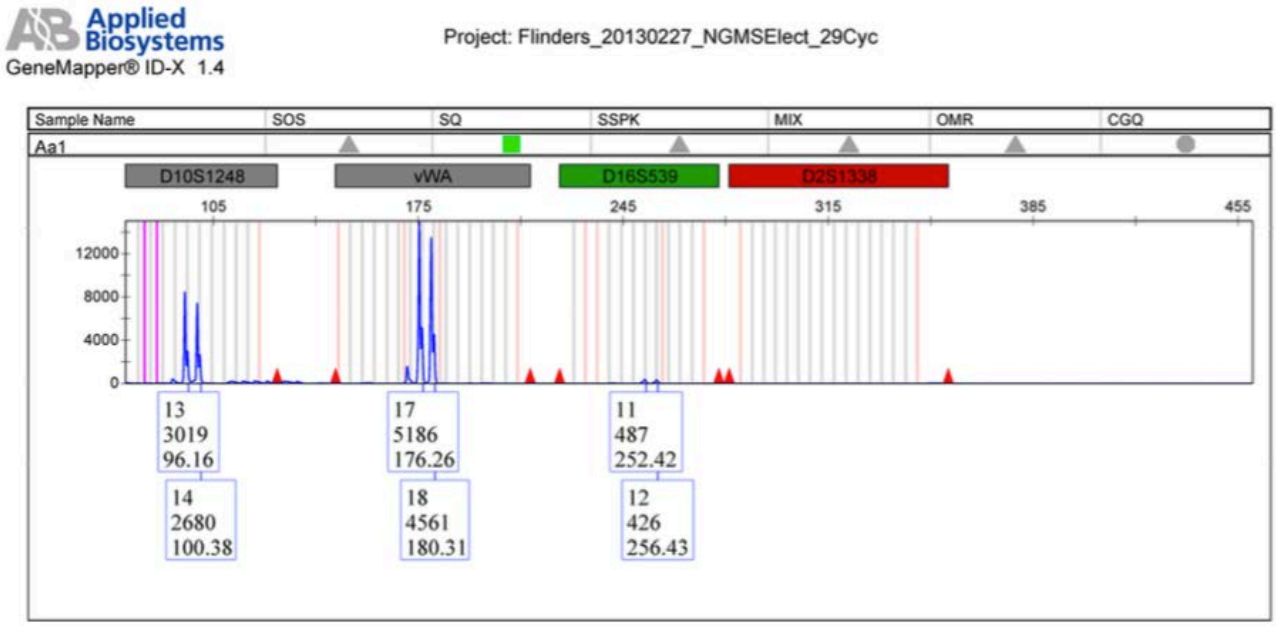

Figure 3.2 – Chromatogram of nuclear DNA from a single anagen hair root amplified using NGM SElect™ PCR kit at 29 cycles on a GeneAmp® System 9700 thermal cycler, without additional AmpliTaq Gold®.

The quality of profile increased when the cycle number was decreased to from 29 to 28 and 27 for GlobalFiler™ Express, and additional AmpliTaq Gold® DNA polymerase was added to the master mix (Figures 3.3 and 3.4).

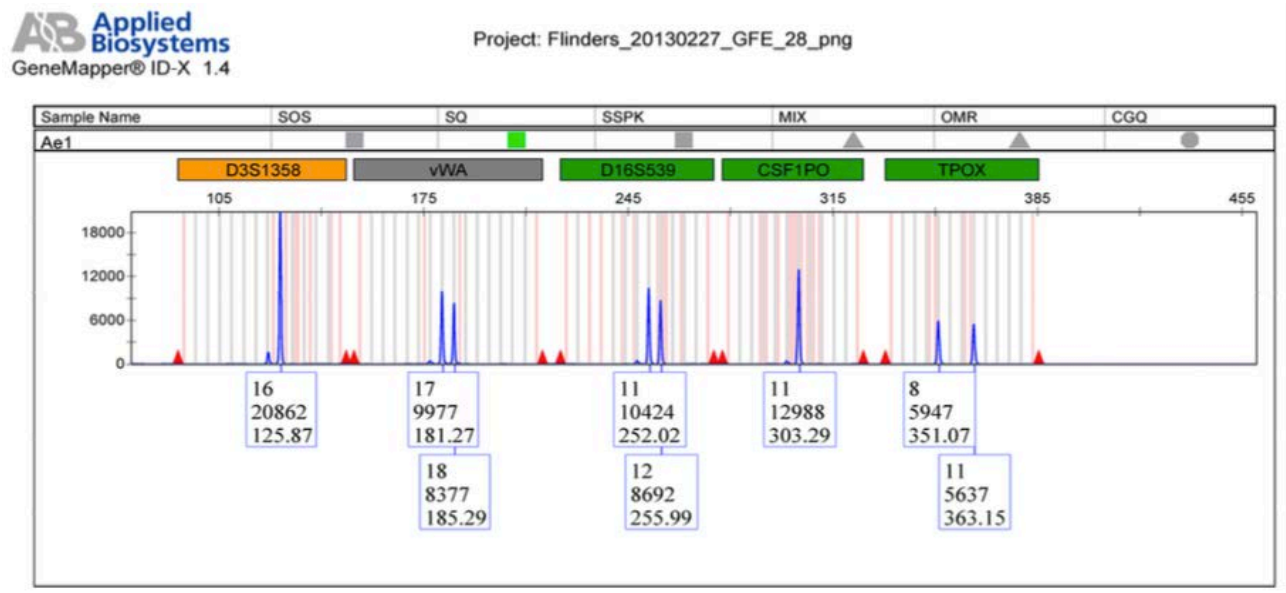

Figure 3.3 – Chromatogram of nuclear DNA from a single anagen hair root amplified using GlobalFiler™ Express PCR kit at 28 cycles on a GeneAmp® System 9700 thermal cycler, without additional AmpliTaq Gold®.

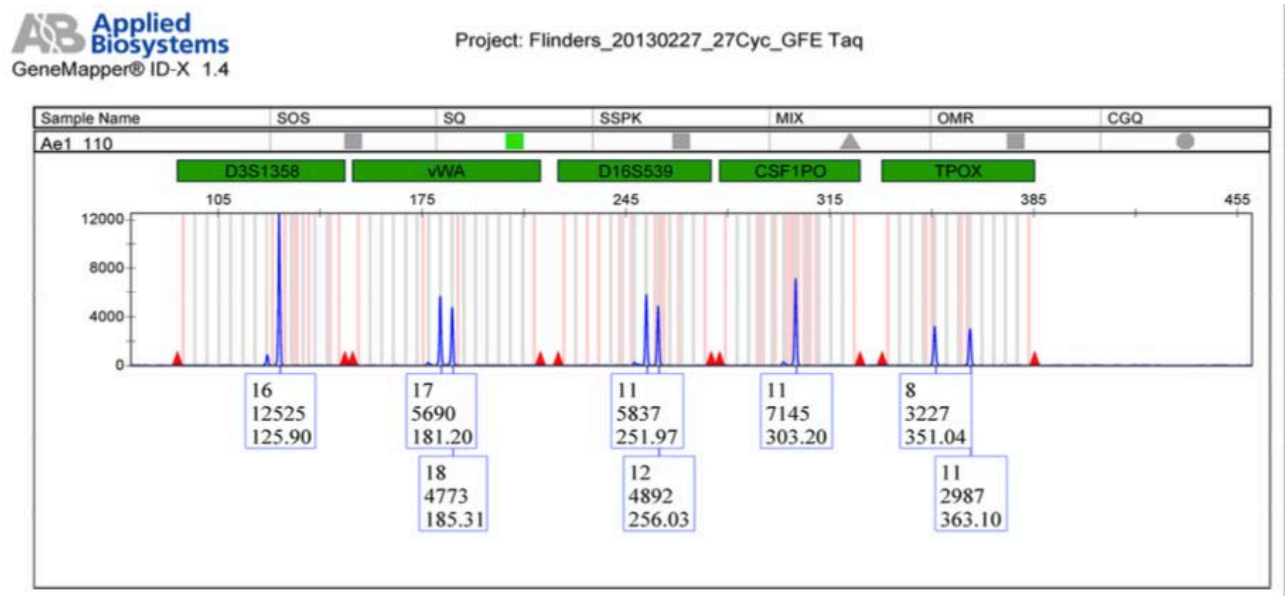

Figure 3.4 – Chromatogram of nuclear DNA from a single anagen hair root amplified using GlobalFiler™ Express PCR kit at 27 cycles on a GeneAmp® System 9700 thermal cycler, with additional AmpliTaq Gold®.

Twelve telogen hairs were sampled with each kit at 29 cycles and there was no significant difference between resulting profiles for either kit used. Using NGM SElect™, one full profile was obtained with an additional four samples returning between 8 – 10 alleles. Likewise for GlobalFiler™ Express, one full profile was obtained with an additional four samples returning between 8 – 11 alleles.

Single anagen and telogen hair results aligned with the data obtained from *section 3.2*, however GlobalFiler™ Express kit has a higher discrimination power with an increased number of loci compared to NGM, with full profiles obtained at a lower cycle number (27) for anagen hairs, therefore reducing the time taken to process samples. Based on the data obtained at the Life Technologies Training Laboratory, telogen hairs still prove to be a challenging sample type from which to consistently obtain meaningful DNA information. Forensic Science SA have also begun to validate the direct PCR technique using hair samples and GlobalFiler™ Express, as the 6-dye technology has become more available.

To assist in improving results obtained from telogen hairs, I travelled to Canberra (ACT, Australia) in February 2015, to explain and help implement the direct PCR technique at the Australian Federal Police forensic laboratory and the National Centre for Forensic Studies (University of Canberra). International forensic student Linda Kron led an experiment under the supervision of Dr. Dennis McNevin to determine the best method for obtaining consistent and meaningful DNA data from telogen hairs.

In order to optimise the success rate, telogen hairs were microscopically classified as either root type 1: the club root without any soft tissue present (most common), or type 2: the club root with a small amount of soft tissue present. Samples were either digested or incubated in TE buffer prior to direct PCR amplification. Other factors were noted to determine if there was an impact on the STR results, such as whether the hairs had been washed or unwashed at time of collection, whether hair roots or shafts were used, or if there was a difference between donors. All samples were amplified using the PowerPlex® 21 System (Promega) following manufacturer's procedures.

Telogen root type 1 hairs (n = 120) produced profiles with six or more alleles in 5.8 % of samples, with only one hair resulting in a full profile. Telogen root type 2 hairs (n = 20) produced profiles with six or more alleles in 20 % of samples, with no samples resulting in a full profile. This gives an average of 12.9 % compared to the 33.3 % success described in *section 3.2.* Although the root types were not classified in *section 3.2*, and may have contained a number of type 3 roots (club root with a large amount of soft tissue present), the large discrepancy between the results is more likely due to the variation in the methods. Additional units of AmpliTaq Gold® was not used in this study, and the direct method does not involve any wash, digestion or incubation step prior to amplification. The addition of these steps is likely to increase the chance of DNA being washed away or lost to the process. It was also observed in this study that the success rate was lower for samples incubated in TE buffer compared to complete digestion.

3.5 Concluding Remarks

Using the direct PCR technique on single human hairs has shown to greatly improve the likelihood of routinely obtaining meaningful DNA information. The simplicity of the technique means validation and implementation within forensic science laboratories can be fast. Significant benefits include the reduction of time and costs involved in the analysis process, allowing for criminal investigations to proceed faster. The preliminary data using aged hair samples demonstrates that this technique can be also applied to cold cases where single hairs have not already been processed for DNA. The investigations conducted at the Life Technologies Training Laboratory and at the University of Canberra strongly indicated that the optimal conditions for sampling human hair using direct PCR should include using additional AmpliTaq® Gold DNA polymerase with no treatments to be made to the hairs prior to amplification. Using direct PCR methods on single telogen hairs, profiles that resulted in enough alleles to be uploaded onto the Australian National Criminal DNA Database (NCIDD) were obtained in approximately 33.3 % of samples, whereas when additional treatment or extraction methods are implemented this is greatly reduced. The study conducted at the University of Canberra included digestion and incubation steps prior to using direct PCR methods, thus decreasing the number of up-loadable profiles to 12.9 %. When extraction and staining methods are implemented, we see a further reduction to 4 % [12] and just 1 % [7] for profiles containing more than eight alleles. As a result of this work, FSSA have verified the same process in-house with an aim to implement the technique into active casework. The technique was officially implemented in July 2015, and approximately 50 hairs have been processed to date, increasing every day.

Introduction

The direct PCR of samples has value in a forensic context due to the potential time saving [1–3], increase in sensitivity, and minimising of steps where potential error or contamination can occur [4]. Previous research has demonstrated the benefit of direct amplification from fibres [4] and touch DNA [5]. To date there has been no testing of human hairs with direct PCR despite the practise of hair sampling during forensic examination [6]. In many forensic laboratories a single hair may not routinely be DNA tested due to the low success rate of obtaining profiles from this medium. We report on the first use of direct amplification of DNA from a single hair in the anagen and telogen growth phases.

Method

- **Samples** A total of 30 anagen and 30 telogen head hairs from male and female donors were analysed. An additional six hairs, (two from each body limb, pubic and eyebrow), that had been stored for 5 years (aged hairs) were also analysed. Growth phase was determined using microscopy.
- **Direct PCR** was conducted by removing approximately 5 mm of the proximal tip using sterile scissors and tweezers. The hair fragment was placed into a 0.2 mL thin walled tube in a volume of 25 µL of PCR mix using either the AmpF*t*STR® NGM™ or NGM Select™ kit (Life Technologies, Victoria, Australia).
- **Amplification** was conducted in a GeneAmp® System 9600 thermal cycler (Life Technologies) using the manufacturer's recommended conditions. The standard 29 cycles was used for all reactions.
- **Analysis:** Samples were run on an ABI 3130*xl* Genetic Analyser (Life Technologies) following standard procedures. The data were analysed using GeneMapper® v3.2. The detection threshold was set at 50 relative fluorescence units (RFU).

Results

- A full profile was obtained from 100% of anagen hair samples and aged hair samples (5 years old). Profiles 'up-loadable' (≥ 12 alleles) to the Australian National DNA Database were obtained for 33.3 % of telogen hair samples. By comparison, when incorporating an extraction step, Forensic Science SA are only able to achieve complete profiles in 53 % of samples for anagen hairs and 10 % for telogen hairs (Table1).

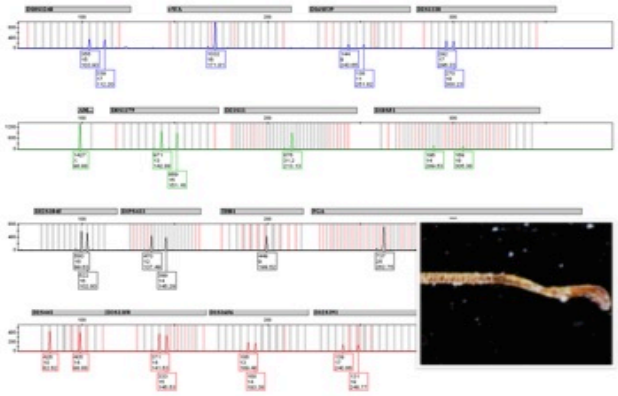

Figure 1. Chromatogram of nuclear DNA from a single **anagen** hair root, amplified using AmpF*t*STR® NGM™ PCR kit at 29 cycles on a GeneAmp® System 9600 thermal cycler. Insert: anagen hair.

Results

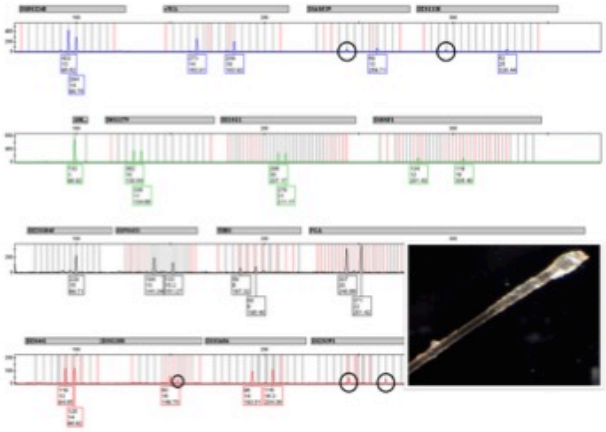

Figure 2. Chromatogram of nuclear DNA from a single **telogen** hair root amplified using AmpF*t*STR® NGM™ PCR kit at 29 cycles on a GeneAmp® System 9600 thermal cycler. Allelic drop out can be observed at the *circled* loci D16S539, D2S1338, D3S1358, and D12S391. Insert: telogen hair.

Table 1. Success rates of DNA profiles obtained from direct PCR of hair at different growth phases. An incomplete and up-loadable profile at FSSA comprises a minimum of 12 alleles including amelogenin. The average RFU values for hairs tested using direct PCR are also shown.

Hair Type	NGM™ and NGM SElect™ profile %			Average RFU
	Complete	Incomplete and up-loadable	Incomplete and not up-loadable	
Anagen	100	0	0	4217
Telogen	20	13.3	66.7	1202
Aged	100	0	0	2929

Concluding Remarks

- DNA extraction was not required to obtain DNA profiles to a forensic standard.
- Complete DNA profiles were obtained from 100 % of anagen hair samples.
- Currently, it is forensic practice not to subject telogen hair for DNA profiling. This study obtained profiles 'up-loadable' to the Australian National DNA Database from 33.3 % of telogen hairs.
- Allelic drop-in or contamination was not observed in any of the 66 DNA profiles obtained from any of the hair samples.
- The standard protocol for DNA amplification from the NGM™ and NGM SElect™ STR typing kits is suitable for direct amplification, allowing for quick and easy implementation into forensic laboratories.
- This method is cost-effective and time saving in forensic casework.
- Full profiles were obtained from aged hairs, making the technique applicable for cold case samples.

We report on successful amplification of DNA profiles from single hairs. Direct amplification was used on the root tip of both anagen and telogen hairs using a standard commercial forensic PCR kit to amplify 15 STR loci. All 30 anagen hairs tested from five different people gave full DNA profiles after 29 cycles with no allelic drop-in or increase in stochastic events. Six of the 30 telogen hairs tested resulted in a full DNA profile, and a further four telogen hair samples tested produced a DNA profile of five or more complete loci that could be uploaded to the National Criminal Investigation DNA Database (NCIDD, Australia). A full DNA profile was also obtained from the shaft of single anagen hairs. Current practice for many laboratories is that single telogen hairs are not subjected to DNA testing and anagen hairs are seldom tested as there is little chance of generating a meaningful DNA profile; hence this 100 % success rate in generating a DNA profile from anagen hairs is a significant advancement. A full DNA profile was obtained from six 5 year-old single hairs illustrating the power of this technique, even on aged or historic samples. The process described was trialled on current DNA profiling kits, using the manufacturer's recommended methods and no increase in cycle number, such that the methodology can be incorporated readily into a practicing forensic laboratory. For the first time in the field of human identification, single hairs can be analysed with confidence that a meaningful DNA profile will be generated and the data accepted by the criminal justice system.

The generation of a DNA profile from trace DNA has become the focus of much interest. The current methodology subjects the sample to a process to isolate the DNA, typically using a solid phase substrate. The aim of this study is to use direct PCR to generate both mitochondrial and STR profiles from latent DNA deposited by touch and also from samples considered to be highly degraded and unlikely to generate a profile if subjected to a DNA extraction process first. Direct PCR has the potential to: minimize loss of target DNA in a critical sample; omit steps involved in standard practice - which will significantly reduce labour time and cost and; increase the likelihood of obtaining a meaningful DNA profile for interpretation. Comparison between the results obtained by direct PCR and from extracts after standard extraction processes indicate the real potential use of the method described in this paper. The technique will have niche future applications in analysing degraded samples that cannot be typed successfully using mainstream, STR-based, kits and protocols.

Abstract

Hairs are encountered commonly in a forensic investigation and can be a source of DNA. The amount of DNA within a single hair is often less than the optimal amount required for nuclear DNA markers. Most of the DNA is within a root sheath with trace amounts of mitochondrial DNA in the shaft. Nuclear DNA testing targets highly repetitive DNA regions called microsatellites. The quantity of starting template required for nuclear DNA profiling is 1 ng, which may be present in the root sheath but not within the hair shaft. Mitochondrial loci are targeted on hair shafts due to their greater copy number.

Glossary

Allele Alternative form of a DNA locus. For example, different lengths of DNA at a short tandem repeat.
Cortex Main body of a hair composed primarily of keratin and containing the pigment granules.
Dithiothreitol A reducing reagent used to break the di-sulfide bridges between the cysteine residues in keratin.
Ethylenediaminetetraacetic acid It chelates positive ions such as calcium and magnesium. It is used commonly in DNA extraction buffers to inhibit naturally occurring DNases (enzymes that destroy DNA).
Microsatellites Sections of highly repetitive DNA and a source of DNA polymorphisms. These are also called short tandem repeats or STRs.
Mitochondrial DNA A circular DNA molecule found in the mitochondria. The molecule is 16 569 bases in circumference in humans and there are 1000s of mitochondria per cell each containing many copies of DNA.
Polymerase chain reaction The enzymatic amplification of DNA.
Sheath Follicular tissue found surrounding a root structure, typically in anagen hairs.
Short tandem repeats (STRs) STRs is another name used for microsatellites.
Sodium dodecyl-sulphate A detergent that is used in DNA extractions as it dissolves the lipid membrane that surrounds many cells.

Background

Hairs are encountered frequently in forensic investigations. As it is estimated that we lose 100 hairs on average each day, these hairs are shed to the surroundings. In a home, shed hair might be noticeable on hairbrushes and combs, but also found on clothing and the fabrics of furniture such as chairs and sofas or automobiles. In sexual assaults pubic hair can be transferred between the assailant and the victim in potentially a two-way transfer. Physical assaults may also result in forcefully removed body or head hair (see Chapter 1 in Butler, 2012 and Chapter 4 in Goodwin *et al.*, 2011).

Prior to the advent of DNA typing, the standard forensic technique for analyzing hairs was by visual examination and then by light microscopy. Clearly if the suspect has long black hair but the hairs under examination from a potential crime scene are very short blonde hairs, then there is no reason to continue with any scientific testing. But if both the reference hairs from the suspect and those from scene are visually similar, then microscopy is a standard technique to allow comparison. A problem is that the hairs of one individual may exhibit much variation within the scalp; the fine hairs at the temple can be different morphologically to those at the nape or at the crown. Even if every morphological characteristic was the same between hairs from a suspect and reference material it is only possible to state that this is not an exclusion. There have been too many false inclusions with opinions provided on matching hairs that in hindsight should not have been given. The examiner might have said "all the morphological characteristics in hairs from the scene are consistent with those from the suspect and therefore they may have a common origin." Post-conviction exonerations using DNA typing, where hair evidence erroneously implicated an accused, has led recently to the focus of DNA typing on hair samples. Opinions

provided in hair comparisons by microscopy were an area of criticism in the report on the state of forensic science in the United States (National Academy of Science, 2009).

Microscopy does still have a role in determining the potential somatic origin (e.g., scalp, pubic, and eyebrow), species (cat, dog, or wildlife), and whether there is cellular material associated with the root (see section below). It is a nondestructive test that remains the standard screening tool to determine if DNA typing is necessary. DNA typing provides an objective scientific test to determine whether an unknown hair and reference sample from an individual match. If they match then a statistical test can be performed to determine if the DNA profiles match by chance. If they do not match then there is a definitive exclusion that the hair did not come from this individual.

Hair Structure

Hair is essentially composed of three structures. The outer surface of the hair is called the cuticle and is typically a thin layer of cells that overlap. In human hairs this looks like slates on a roof but there is a very wide variation in cuticle patterns between different mammalian species. The cortex is the main component of the hair and is primarily composed of a protein called keratin. Keratin is the same protein found in nails, hoofs, antlers, and horns. Keratin proteins tend to be very long chains of amino acids but multiple chains can bond together (analogous to multiple pieces of string wound around each other to make rope). Keratin has a high content of the amino acid cysteine. Cysteine is the only one of the 20 naturally occurring amino acids that has a sulfur residue and when a sulfur on one keratin chain lies next to a sulfur on another, the two sulfurs can bind together making a strong disulfide bridge. Within the cortex are the pigment granules that are responsible for giving the hair its color. In humans, the pigment granules are evenly spaced giving the same color throughout the hair whereas many animal hairs have a banded coloration. At the center of the hair is the medulla; this is a thin air-filled shaft that gives the hair extra strength. Under light microscopy the medulla appears as a dark core.

Of relevance to DNA typing, DNA can be found in the cortex due to residual cells that are responsible for the growth and development of the hair. DNA has not been reported to be found in the air-filled medulla although cells are regularly found adhering to the outer surface of the cuticle (see for instance Chapter 8 of Saferstein, 2007).

Hairs may also be used for forensic toxicology analysis due to their unique matrix. As hair has no active metabolism or method for secretion, unlike blood or urine, drugs will remain in the hair for longer periods once deposited and can help in investigations such as suspected poisoning or accidental drug exposure.

Hair Growth Phases

Hairs have a finite lifespan starting with active growth, then senescence, and ultimately release from the skin. The active growing phase is called anagen, with hairs in this phase called anagenic. Typically hairs grow for about 1000 days and approximately 90% of scalp hairs are anagenic. Hairs grow from their base within the scalp, called the follicle, due to the rapid replication of the germinal cells and melanocytes. As the cells replicate and divide at the base of the hair, the old cells are pushed upwards into the growing structure of the hair and are ultimately keratinized leading to the disruption of the cell and cell death. The melanocytes and germinal cells are the source of DNA later found in the cortex of the hair, as the cellular DNA from these two cell types remains associated within the keratin or cortex. When hairs reach the end of their growth phase the follicle starts to shrink and lose contact with the surrounding epidermal cells. There is a very short period lasting only a few days, called catagen (catagenic hairs), where the hairs are in the intermediate state before the last phase called telogen. Telogenic hairs account for the majority of the remaining 10% of hairs, with less than 1% being catagenic as this phase may only be a few days in duration. During the telogen phase a new follicle starts to develop below the older one leading the shrinking of the old follicle, detachment from the dermis, and then to the hair being shed. Typically it is the telogenic hairs that are encountered at crime scenes, as these are the most likely ones to be shed naturally.

A telogenic hair has a distinctive follicular tag at the root end. This is in contrast to the root end of an anagenic hair where a visible cellular sheath may be present. This simple differentiation, which is determined by microscopy, can be valuable in a forensic investigation as the presence of an anagenic hair indicates it was most likely forcibly removed. An example of hair roots from these three growth phases is shown in Figure 1.

DNA within Hair

The hair shaft is known to have very little DNA as this is only the residual DNA from the melanocytes and germinal cells. This is in contrast to the root which, if present, is potentially a rich source of DNA.

DNA typing is predominantly based on analyzing genetic markers in the nucleus. Nuclear DNA is rarely found associated with the hair shaft in sufficient amounts to generate a DNA profile. The alternative DNA typing targets the mitochondrial DNA. As explained below, mitochondrial DNA is found in larger

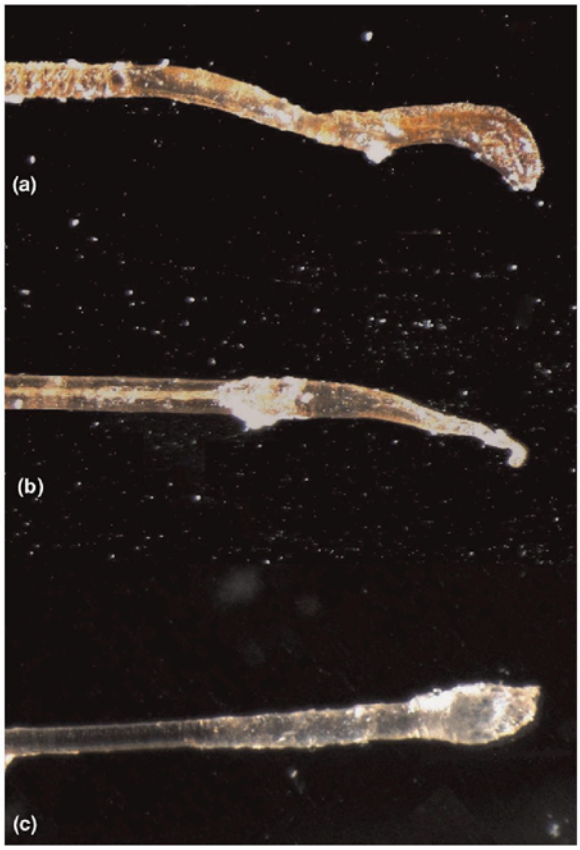

Figure 1 The three stages of hair growth: (a) anagenic hair with sheathing present, (b) catagenic hair with thin tapered root, and (c) telogenic hair with club or bulb shaped root. Images captured by Renée Ottens.

amounts than DNA from the nucleus and also is found in the shaft of telogenic hairs.

Nuclear DNA

DNA profiling methods and DNA databases are based on microsatellites (otherwise termed short tandem repeats (STRs)) on the autosomal chromosomes. Each person has two copies of their nuclear DNA, with one copy from the mother and the other from the father. Typically, most commercial STR testing kits require 1 ng of starting template. This mass of DNA equates to approximately 170 human cells. It is unlikely that this amount of DNA will be found in hair shafts and hence nuclear STR testing is unlikely to generate a DNA profile from a single anagenic or telogenic hair shaft. A single fresh anagenic hair, where a clear root sheath is visible, has the potential to generate a DNA profile. A single telogenic hair root is, however, very unlikely to have sufficient DNA to generate a profile. It is not good practice to group together numerous telogenic hairs to obtain sufficient DNA as the hairs may have come from more than one person.

Analysis of Nuclear DNA

A decision needs to be made as to whether there is any chance of generating a DNA profile using nuclear markers. If there is a visible root then this terminal section of the hair (approximately 3 mm) should be cut into a sterile tube. The cells in the root sheath should be treated like any skin cells. Typically a detergent such as sodium dodecyl-sulphate (SDS) is used to break open cell membranes and a chemical called ethylenediaminetetraacetic acid is used to remove magnesium and calcium ions (the removal of magnesium ions stops naturally occurring DNases from breaking down the DNA). Typically to ensure that all of the DNA is released from the hair section, the enzyme proteinase K (so called as it digests keratin) and a reagent such as dithiothreitol (DTT) that breaks the disulfide bridges are added. The hair shaft is incubated in this extraction buffer until the hair shaft is no longer visible. The released DNA can then be isolated using one of the commercially available kits which use a positively charged solid phase to bind DNA; the DNA can later be released into a new solution by altering the charge of the solid phase to neutral.

The isolated DNA can then be quantified during a standard process and then subjected to DNA profiling using a commercially available kit. All the kits for DNA profiling analyze STR loci. These are regions on a chromosome where a sequence of DNA bases is repeated multiple times; the number of times the repeat is found can be variable within the population. For instance there is a tiny section of chromosome 16 that has the sequence GATA where some people carry 4 GATAs (GATAGATAGATAGATA), some 5, some 6, and indeed all the possible types (alleles) to 17 repeats. As there are a total of 14 alleles (4–17) then there is in fact 105 potential genotypes. This is an example of one STR locus, however, there are commercial kits that analyze 21 STRs leading to astronomical powers of discrimination (the chance that someone else shares the same genotype at all 21 STR loci). All of the DNA databases constructed from persons who have committed a crime are based on nuclear STR typing; hence there is a significant reason to employ this type of genetic marker if possible. If there is less than 170 cells worth of DNA, and the DNA quantification results indicate that there is 200 picograms of DNA present, then is can still be tested using these STR markers. In such a case it is highly likely that not all the STR loci will generate a result leading to what is termed a partial DNA profile. If only five of the loci tested generate a result, and the others generate no data as is typical with less than optimal DNA being isolated, then this can still have a power of discrimination of more than 1 in 10 million.

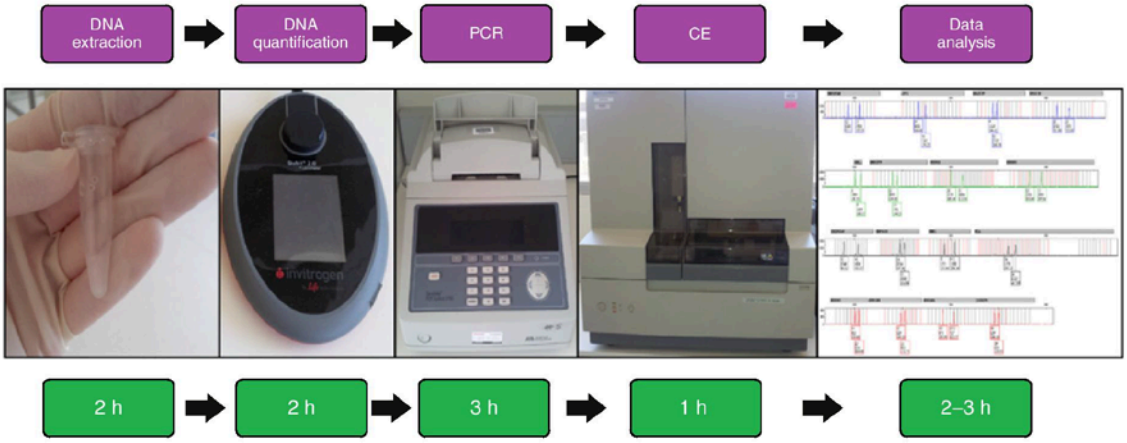

Figure 2 The standard process for DNA analysis showing the time taken for each step from DNA extraction through to data analysis. The process takes a minimum of 10 h and includes 5 steps along the process. Images captured and created by Renée Ottens.

A standard timeline for the STR typing of hair fragments is shown in Figure 2 (for more information see Chapter 6 of Goodwin *et al.*, 2011).

Mitochondrial DNA

If nuclear DNA testing is not an option, such as when there is no root sheath and the hair appears to be telogenic, then mitochondrial DNA testing is an option. Mitochondrial DNA is present in much higher copy number than nuclear DNA; typically there can be over 10 000 copies of mitochondrial DNA in one cell compared to two copies of nuclear DNA. Additionally mitochondria, the cellular organelle responsible for respiration, have a strong protein coat that protects the internal DNA from bacterial degradation.

Mitochondrial DNA testing is used less than nuclear STRs due to the mode of inheritance and resulting power of discrimination. Mitochondria and their DNA are present in the cytoplasm of the egg cell but spermatozoa do not contribute mitochondrial DNA to any fertilized embryo; hence all mitochondrial DNA comes from the mother and not the father. This can be a real advantage as everyone who shares a maternal relative will have the same mitochondrial DNA leading to linkage between a hair sample and a great granddaughter for instance. This sharing of mitochondrial DNA sequences is also the disadvantage as the power of discrimination (i.e., how many other people share the same DNA type) is poor as mitochondrial DNA cannot differentiate brothers and sisters, mother, and daughters, or even more distant genetic relatives if they share a maternal relative.

Mitochondrial DNA has been used in historic cases such as the identification of the Russian royal family who were murdered in 1918 and their skeletal remains not recovered until 1989. Here mitochondrial DNA from living known genetic relatives provided mitochondrial DNA profiles to allow matching to confirm the identity of the Tsar and his family (discussed in Chapter 13 of Goodwin *et al.*, 2011). The high copy number is also an advantage when the DNA is highly degraded such as in the body parts retrieved from the World Trade Center victims in 2001 and maternal relatives.

As mitochondrial DNA is inherited from the mother only and there is no recombination of the DNA (as happens with nuclear DNA), then all cells of an individual will have the same DNA type. This single version is called a haplotype and many of the haplotypes are known and mapped for populations around the world. This has the potential for an unknown mitochondrial DNA type to be placed within a geographical location based on common maternal ancestors.

Analysis of Mitochondrial DNA

Mitochondrial DNA typing is more likely to be performed on telogenic hairs or if there is no obvious root sheath to a hair. The extraction process is typically the same method as for nuclear DNA typing. The analysis of mitochondrial DNA is very different as it is based on variation of the DNA sequence rather than the length (as in the number of STR repeats in nuclear DNA typing). Mitochondrial DNA is a circular molecule unlike chromosomal DNA. The human mitochondrial DNA is around 16 569 bases in circumference and almost all of it is very similar between every human. Much of the DNA sequence of the mitochondrial genome encodes for genes and is under very strong selection pressure to stay the same. Any change due to a mutation in the coding region has the potential to alter the encoded amino acid which can in turn lead to an alteration in the performance or function of the protein. There are two short

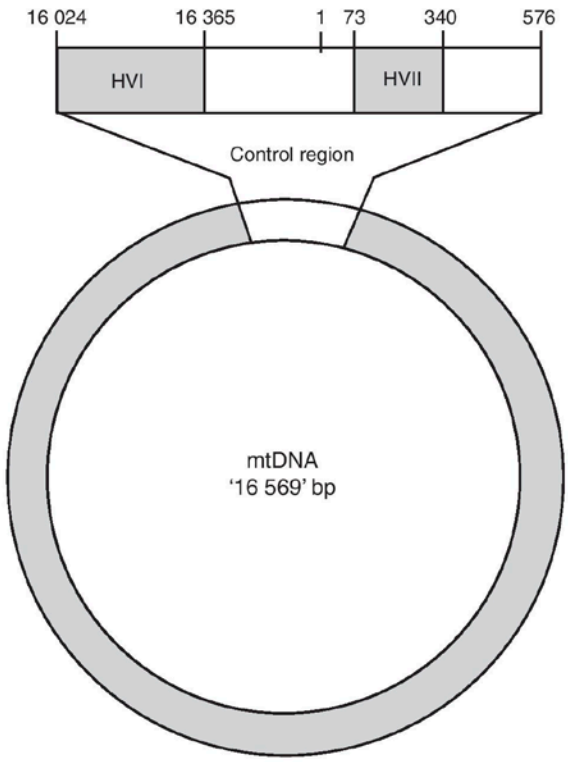

Figure 3 The hypervariable regions of the mitochondrial DNA genome showing the locations of the hypervariable regions 1 and (HVI and HVII). The entire circular mitochondrial genome is 16 569 bases in circumference and all the bases have been mapped and numbered from position 1 to base 16 569. Image created by Renée Ottens.

stretches of DNA bases within the mitochondrial DNA that do not encode a protein and these regions show sequence variation between people (who do not share a recent maternal relative). These are called the hypervariable region 1 (HVI) and hypervariable region 2 (HVII). See Figure 3 for a diagram of HVI and HVII.

In the process of DNA typing it is only these short sequences that are determined by a routine process called DNA sequencing. If the DNA sequences differ then this is an exclusion; i.e., the hair could not come from the same source as the reference material. If the HVI and/or HVII DNA sequences of a hair sample have the same DNA sequences as a reference sample then this is an inclusion. In the event of an inclusion there are three possibilities to consider: either the hair comes from the same person as the reference sample, or it comes from another person with a recent maternal relative, or it comes from someone else and matches by chance. The only difficulty is if there are one or two bases different over the 610 bases that constitute HVI and HVII. The possibility that these differences are due a mutation in the DNA sequence (changed at this one base) when passed from the mother to the offspring needs to be considered.

Mitochondrial DNA also suffers from a problem of sequence variation within the same person. This is a somatic mutation where two or more sequences exist and it is called heteroplasmy. When cells are dividing rapidly such as in melanocytes then during cell replication it is possible that a mutation occurs at a single base leading to a new bases in this mitochondrial DNA. If this mutation happens in one new cell but not in another then the result can be heteroplasmy.

Animal Testing

Dog and cat hairs are found frequently on clothing or at crime scenes and there can be associative evidence if linked to an individual animal. Microscopy can determine if a hair is from a particular species using the overall shape (most animal hairs taper at the tip whereas only human eye bow hairs show this tapering), the cuticle pattern, and the size and pattern of the medulla (in humans it is less than a third of the total diameter of the hair but in cats, rabbits, deer it can be large and lattice shaped).

Animal hairs can be subjected to the same DNA tests as human with the same choices of either nuclear DNA typing or sequencing part of the mitochondrial genome. A set of STR loci are in place for both dogs and cats and there are databases of the allele frequencies and occurrence of haplotype for both these species being developed.

New Technologies

DNA isolation methods described above are designed to extract DNA from the cortex and then purify the nucleic acid to remove any inhibitors of the amplification process. The procedures are very inefficient with up to an 85% loss of the DNA. The result is that there may be 150 cells for instance, equating to just less than 1 ng of DNA, in the starting sample but after DNA extraction and losing 75% of sample, the final extract only has 0.25 ng of DNA (or 250 pg). This is unlikely to generate a full DNA profile.

Many forensic science laboratories will not subject a single anagen hair to nuclear DNA testing as it is unlikely to generate a result. Such a sample may contain pertinent information for the investigation.

A novel approach in such cases is termed direct polymerase chain reaction (PCR) where a section of hair is placed directly into the PCR with no extraction process. The first step in using hot-start DNA polymerases is to heat the solution for 10 min at 95 °C to activate the enzyme. The heating process also denatures the proteins in the hair resulting in the loss of DNA into the solution. The benefit is that there is no loss of DNA prior to this step, and all the material is added to the reaction.

The disadvantages are that the test cannot be reproduced as all the sample is used, and if there are inhibitors present then no PCR products may be generated.

The process of direct PCR has been shown to work on single hairs over 5 years old and can be used in cold cases where no other method is available.

Molecular biology has witnessed tremendous advances in DNA sequence technology in the last few years with the advent of mass parallel DNA sequencing (often called high through-put sequencing or next-generation sequencing). Whole genomes can now be decoded in a matter of hours rather than the 3 years it took for the first human genome to be sequenced. Single cells can be used in such applications leading to open the opportunity to sequence the entire DNA content rather than target only mitochondrial DNA or the microsatellites. At the time of writing, such technologies are still too expensive to be performed regularly but there is every possibility that they will become a routine tool once the costs are reduced.

Direct PCR from Canine Hair

4.1 Preface

Human hairs are not the only hair types found at crime scenes, it is also common to encounter animal hairs from cats, dogs or rabbits within a home, vehicle or on clothing [1-3]. Domestic animal hair can be found in abundance around the home and is easily transferred to other surfaces and areas via direct contact or secondary transfer, as most domestic pets can shed their coats several times a year with season changes [3]. Microscopy is often used to determine the type of animal hair found based on its morphology, as each species possess hair with characteristic length, colour, shape, root appearance and internal distinguishable microscopic features [1, 2]. Microscopic comparisons can be a great tool in potentially linking crime scenes, suspects and victims, but do not have the same level of discrimination power of DNA analysis. Autosomal STR markers have been researched and identified for canine and feline DNA, however the multiplex assays are not commercially available to the same extent as those for human identification. The demand and need for human DNA analysis is obviously much greater than that of animal DNA analysis, however crime scenes may arise where single animal hairs are the only physical evidence available for analysis. Like human hairs, animal hairs can be considered trace evidence and again are very difficult from which to obtain meaningful DNA information [4]. To provide DNA analysis from single animal hairs would offer investigations another powerful tool in solving cases or generating leads. The following sections investigate the optimisation of the canine STR markers within the Flinders University DNA laboratory (*4.2*), the application of canine hairs as a substrate for direct PCR (*4.3*), as well as the application of canine STR markers in casework and future implementation of the technique (*4.4*).

4.2 Multiplex setup

DogFiler is a multiplex assay developed for canine DNA profiling in forensic casework, encompassing 15 loci and one sex-determining marker [5]. To determine whether canine hairs are a suitable substrate for direct PCR methods, eight loci (including the sex-determining marker) were chosen for preliminary testing. Information regarding the optimal canine DNA concentration for use with DogFiler, or the primer concentrations of the multiplex has not been published and needed to be optimised before amplifying substrates directly. The optimal DNA concentration for human identification kits is on average 1 ng. Humans have 23 chromosomal pairs whereas canines have 39 chromosomal pairs, therefore it can be expected that the optimal DNA input for DogFiler will differ because of this difference.

Phusion® High-Fidelity DNA Polymerase (Thermo Fisher Scientific, Victoria, Australia) and QIAGEN® multiplex PCR kit (Qiagen, Victoria, Australia) were compared to determine which DNA polymerase is most suitable for canine DNA amplification. Following manufacturer's instructions for a final PCR volume of 26 µL, 2 ng of control canine DNA was amplified using Phusion® and QIAGEN® multiplex assays (Figures 4.1 and 4.2, respectively). QIAGEN® overall performed better than Phusion®. Profiles obtained using the Phusion® assay often displayed noisy baselines, split-peaks, and greater loci and allele imbalance than profiles obtained using the QIAGEN® assay. Using positive control DNA, primer concentrations were adjusted until a balance between the amplicons of the eight STR loci was observed. All final primer concentrations, primer information, PCR set-up and PCR conditions are outlined in *section 4.3*.

Using the QIAGEN® multiplex assay, canine DNA was amplified at 4, 3, 2, 1 and 0.5 ng to determine the optimal input concentration (Figure 4.3). At 2 ng and 3 ng of input DNA, balanced heterozygous allele peaks with strong RFU values averaging 6000 – 7000 were consistently obtained. At 4 ng of input DNA, baseline noise and the effects of pull-up were more noticeable, with the peaks occasionally presenting as split. At 0.5 ng of input DNA, full profiles could still be obtained, resulting in average RFU values of 2000. Peak imbalance was more common at 0.5 ng of input DNA. All concentrations resulted in full profiles, with alleles clearly defined; even at higher concentrations the baseline noise and pull-up were minimal. There was little difference overall with profile quality between 1 – 3 ng of DNA, therefore the optimal input using the eight loci selected with the QIAGEN® multiplex assay would fall within this range.

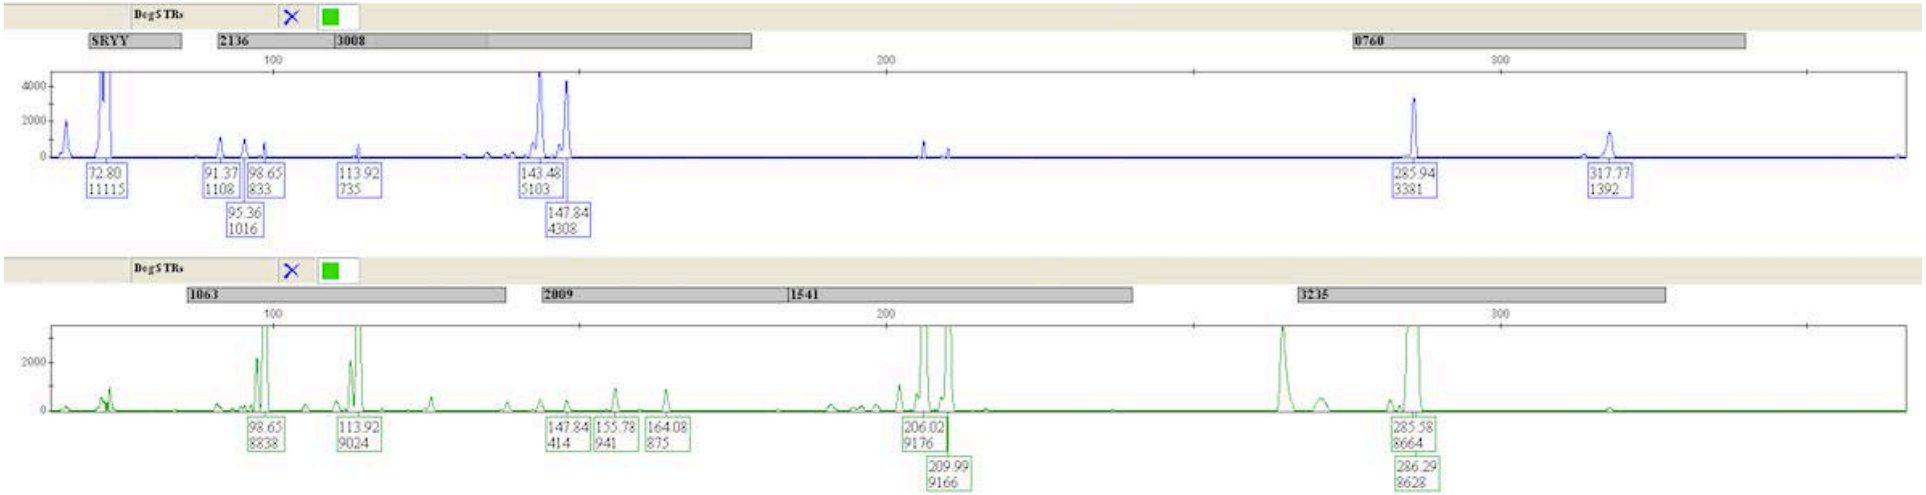

Figure 4.1 – Chromatogram of nuclear canine DNA (2 ng) amplified using Phusion® High-Fidelity DNA Polymerase and DogFiler loci at 31 cycles on a GeneAmp® System 9600 thermal cycler.

Figure 4.2 – Chromatogram of nuclear canine DNA (2 ng) amplified using QIAGEN® multiplex PCR kit and DogFiler loci at 31 cycles on a GeneAmp® System 9600 thermal cycler.

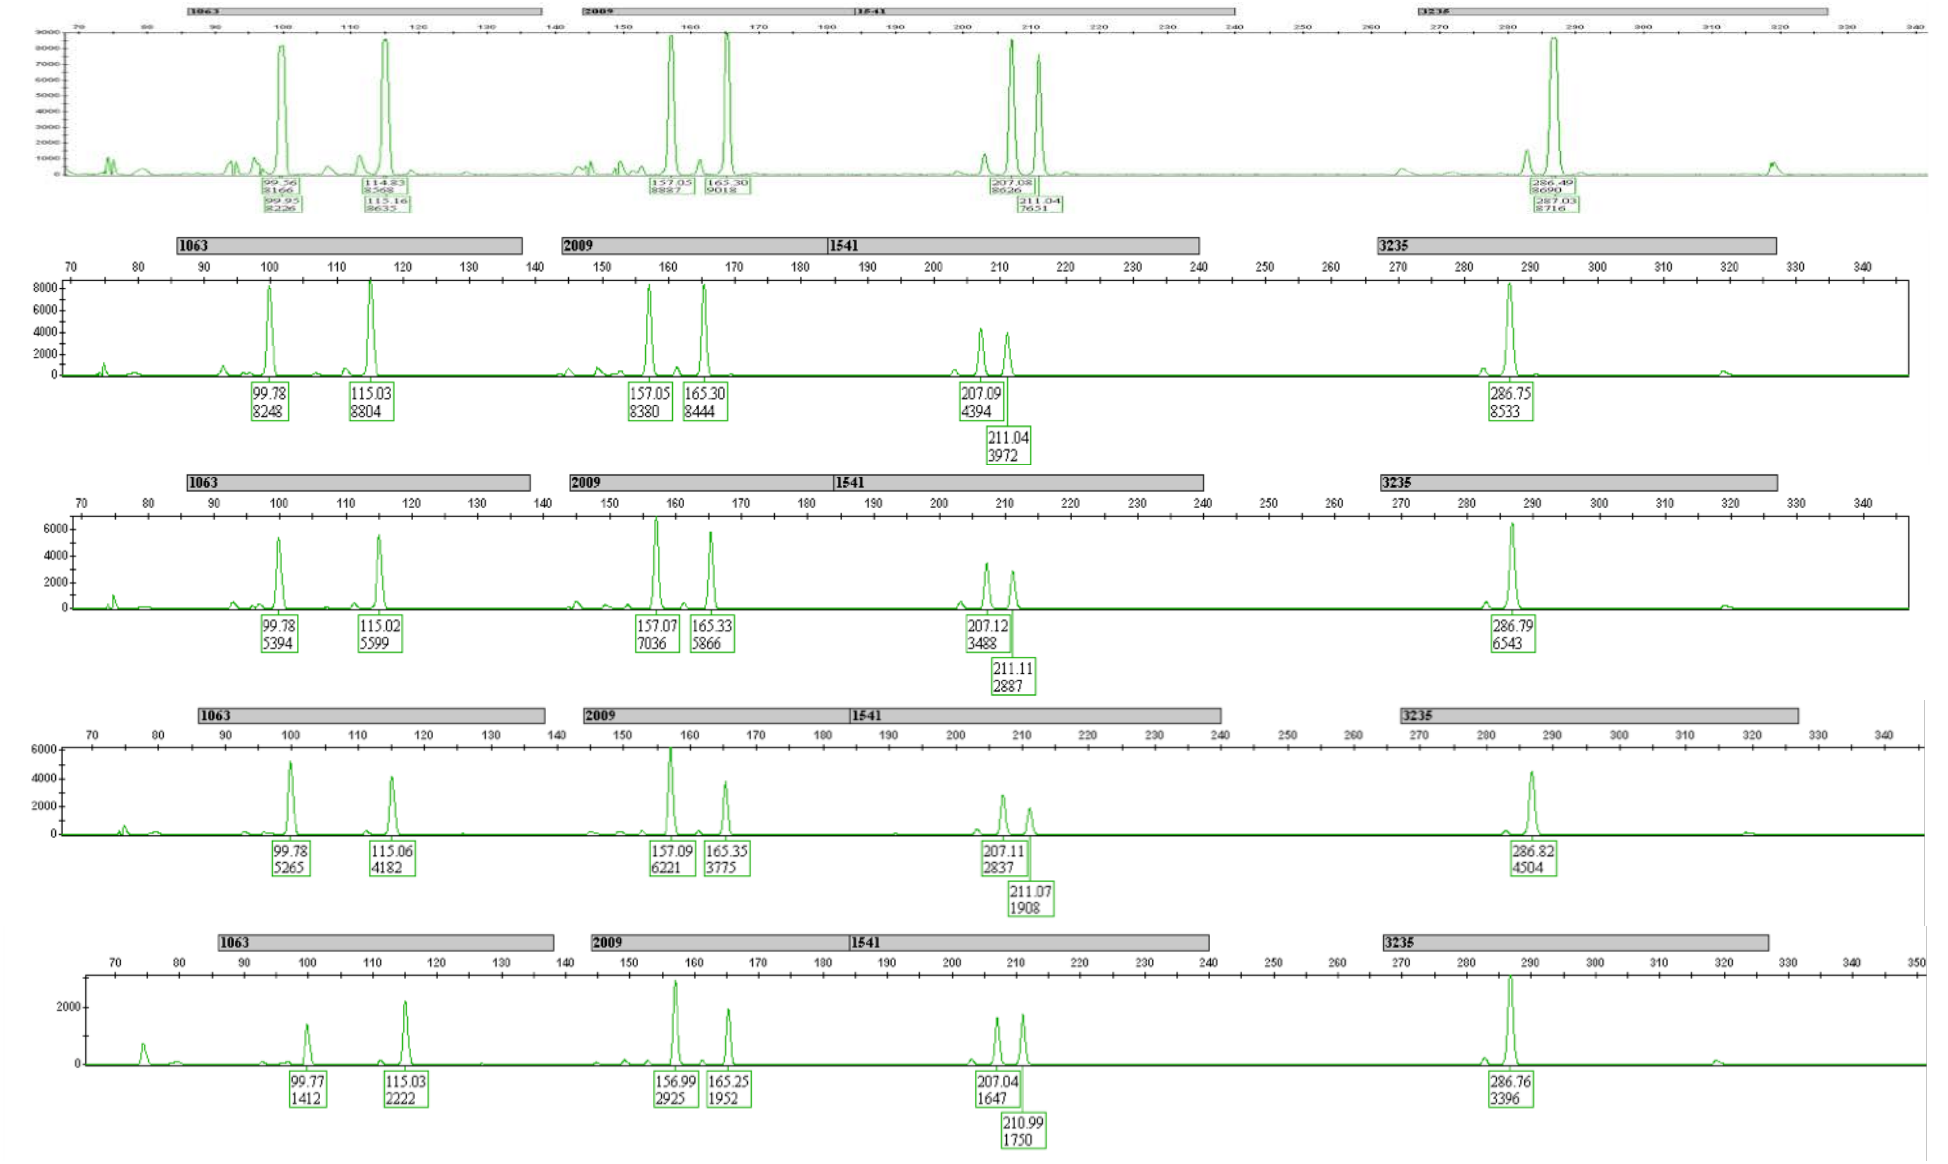

Figure 4.3 – Five chromatograms of nuclear canine DNA at concentrations: 4 ng, 3 ng, 2 ng, 1 ng and 0.5 ng (top to bottom), amplified using QIAGEN® multiplex PCR kit and DogFiler loci at 31 cycles on a GeneAmp® System 9600 thermal cycler.

Shed telogen animal hairs would represent the majority of animal hair types assessed in casework and are therefore the focus of this preliminary study. To determine if there was any substantial difference in obtaining DNA profiles between canine telogen and anagen hairs, both types were analysed using microscopy and amplified directly. Animals do not have their coats washed as regularly as humans wash their hair, with animal hair more likely to retain nuclear DNA and cell-free DNA along the shaft due to skin secretions, and saliva from grooming. To increase the likelihood of obtaining DNA from telogen canine hairs, an entire hair was cut into ~ 5 mm sections and amplified in one 0.2 mL tubes (Figure 4.4)

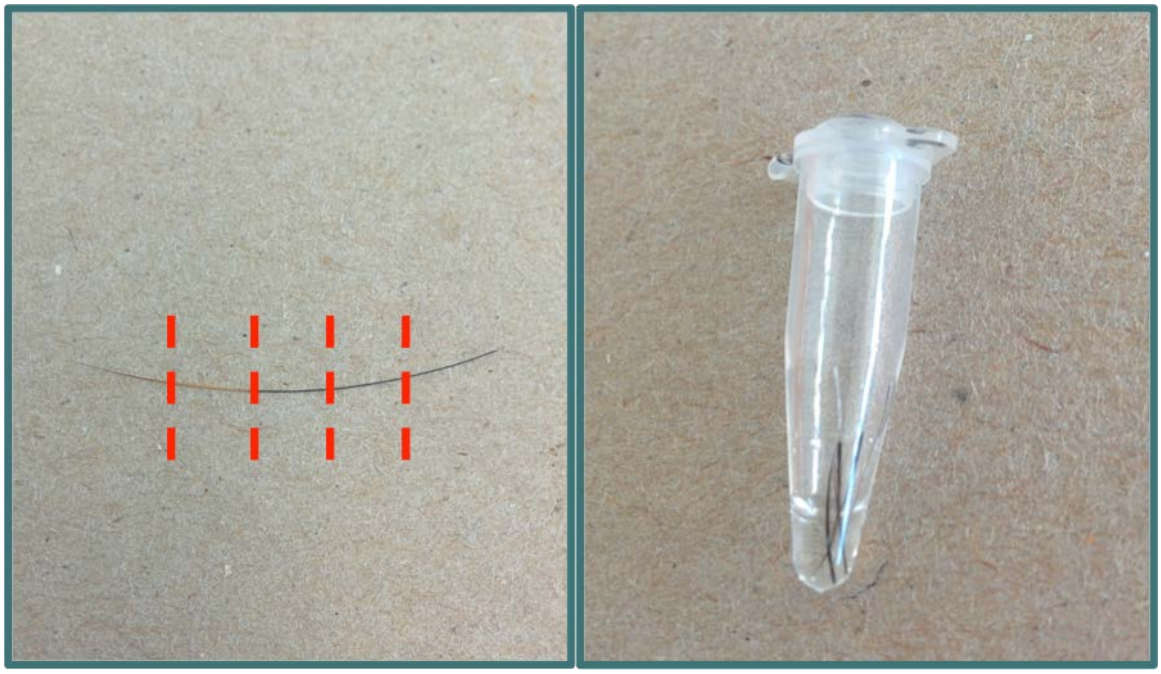

Figure 4.4 – A single canine hair (telogen) showing the approximate cut sections, and the resulting hair fragments within a 0.2 mL PCR tube containing 26 µL of QIAGEN® multiplex assay master mix and DogFiler primers.

Anagen and telogen canine hairs resulted in full profiles, displaying clear baselines and alleles (Figure 4.5). There was no significant difference in profile success rate between the two hair types during this preliminary study, indicating that there is more DNA found on the shaft of an animal hair than a human hair (again, possibly due to the frequency of washing, or animal grooming habits). As telogen hairs are more common at crime scenes, with the preliminary data showing that this hair type produces similar results to anagen hairs, *section 4.3* focuses on shed hairs only.

Canines may have several different coats of hair that are shed differently depending on the weather, mainly comprised of an undercoat and a topcoat. The undercoat is generally soft, thin and fluffy, whilst the topcoat (also referred to as guard hairs) is thicker and coarser (Figure 4.6).

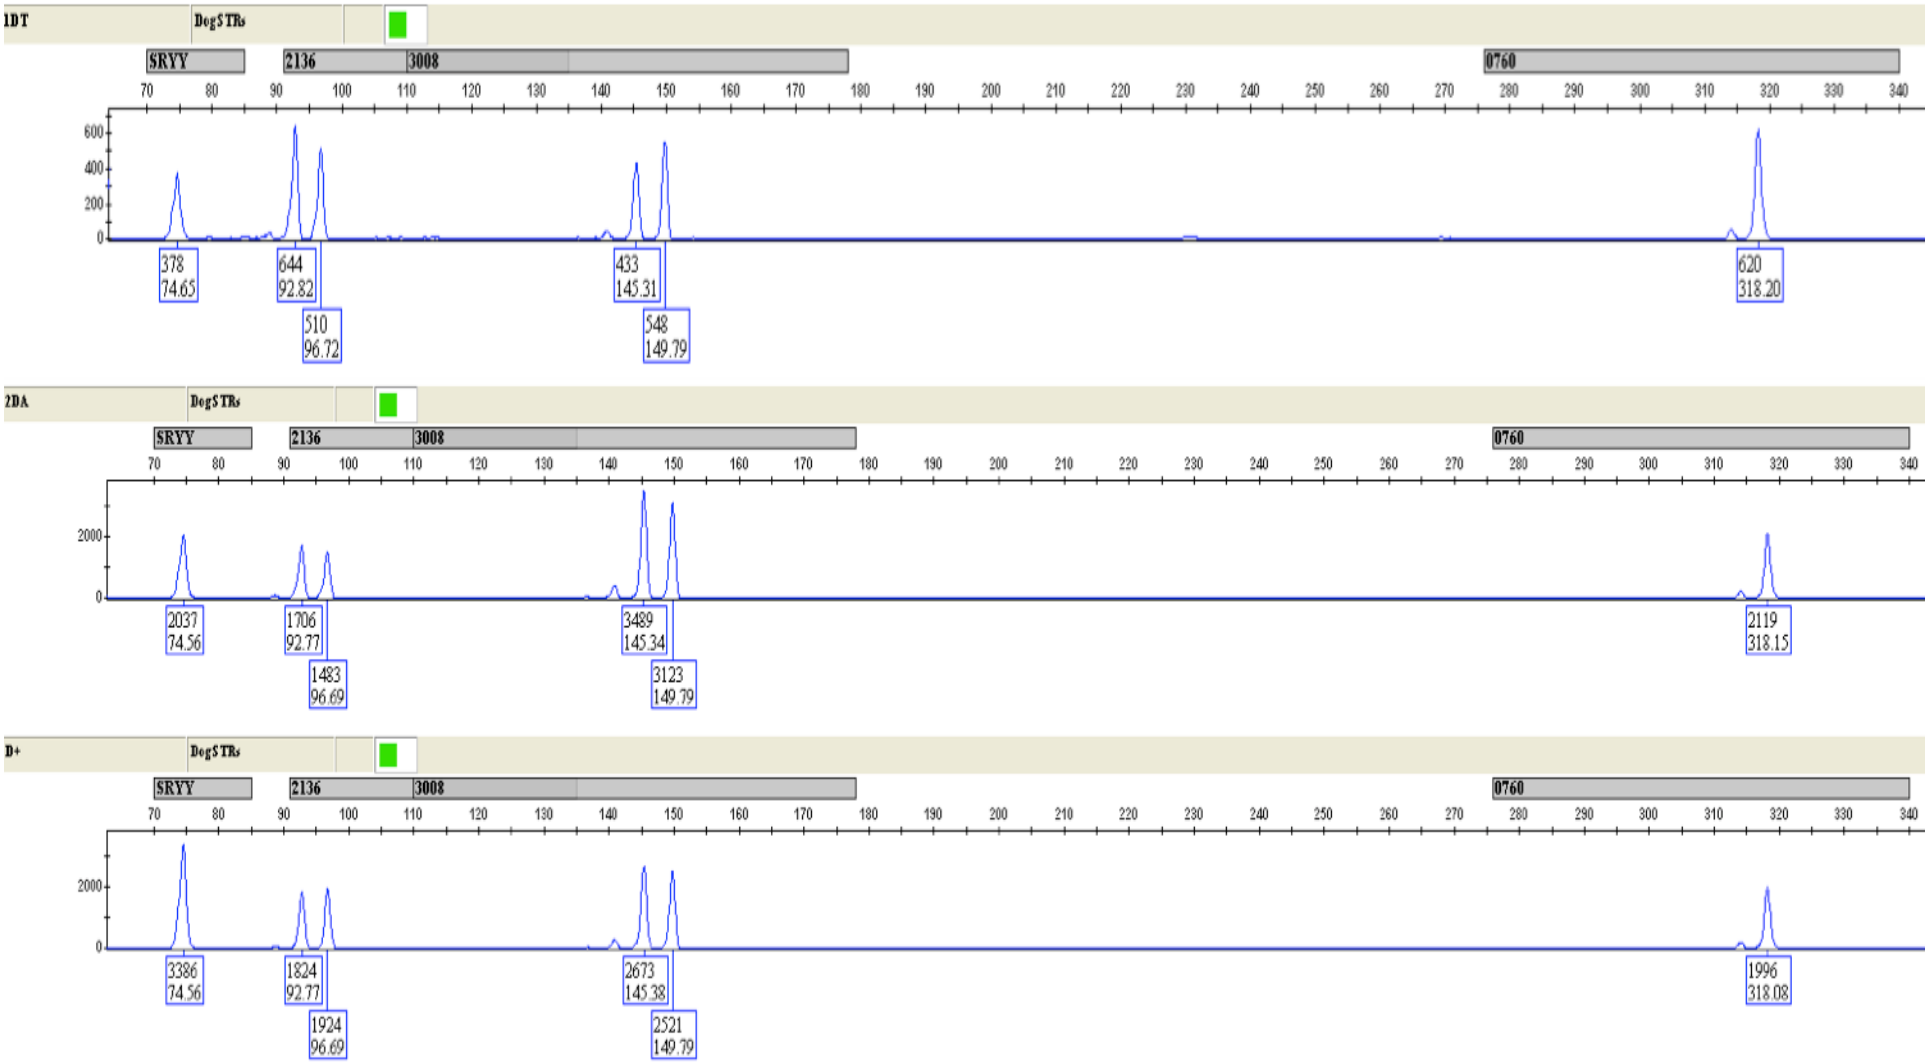

Figure 4.5 – Three chromatograms of nuclear canine DNA samples: telogen hair, anagen hair and positive control (top to bottom), amplified using QIAGEN® multiplex PCR kit and DogFiler loci at 31 cycles on a GeneAmp® System 9600 thermal cycler.

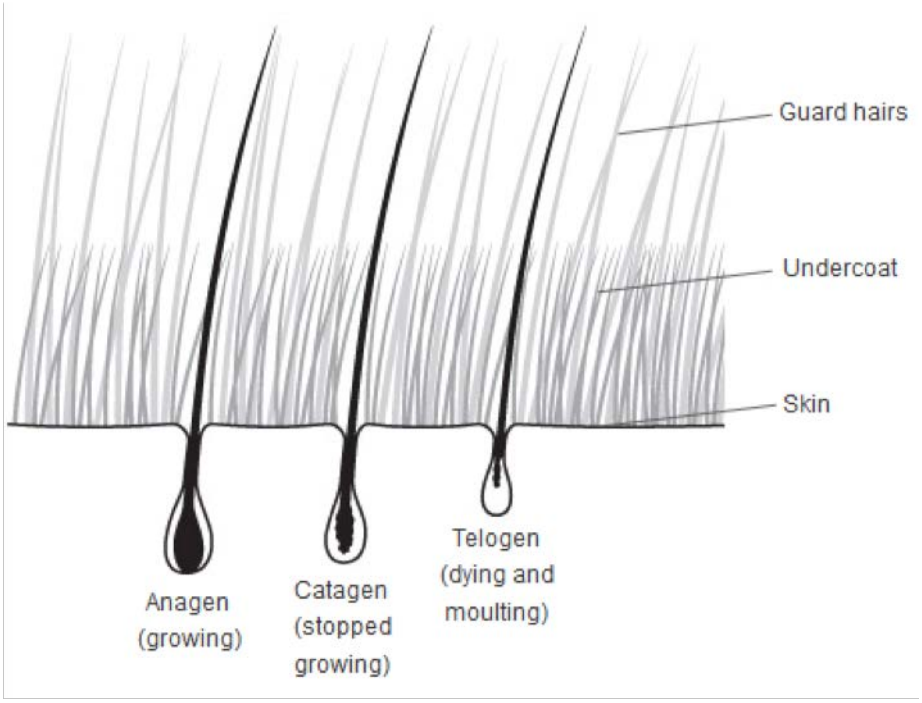

Figure 4.6 – Three stages of hair growth (anagen, catagen and telogen), showing the height and density difference of a canine's undercoat and topcoat (guard hairs). *Figure source: https://www.dyson.com.au/pets/dog-grooming.aspx*

Preliminary canine hair testing concluded with the amplification of undercoat and topcoat hair samples. Single topcoat hairs were prepared as per Figure 4.4, however due to the thin and static nature of undercoat hairs, more were added to the 0.2 mL PCR tube. Small tufts of approximately ten hairs were used instead of a single hair in order to increase the amount DNA available for amplification. Undercoat hairs showed higher signs of peak imbalance and allelic dropout than topcoat hairs, yet still resulted in full profiles for most samples tested (Figure 4.7).

With the DogFiler multiplex optimised for use, and the knowledge of what hair types are successful, a more in-depth study was conducted (*section 4.3*) to discover the full potential of using canine hairs with direct PCR.

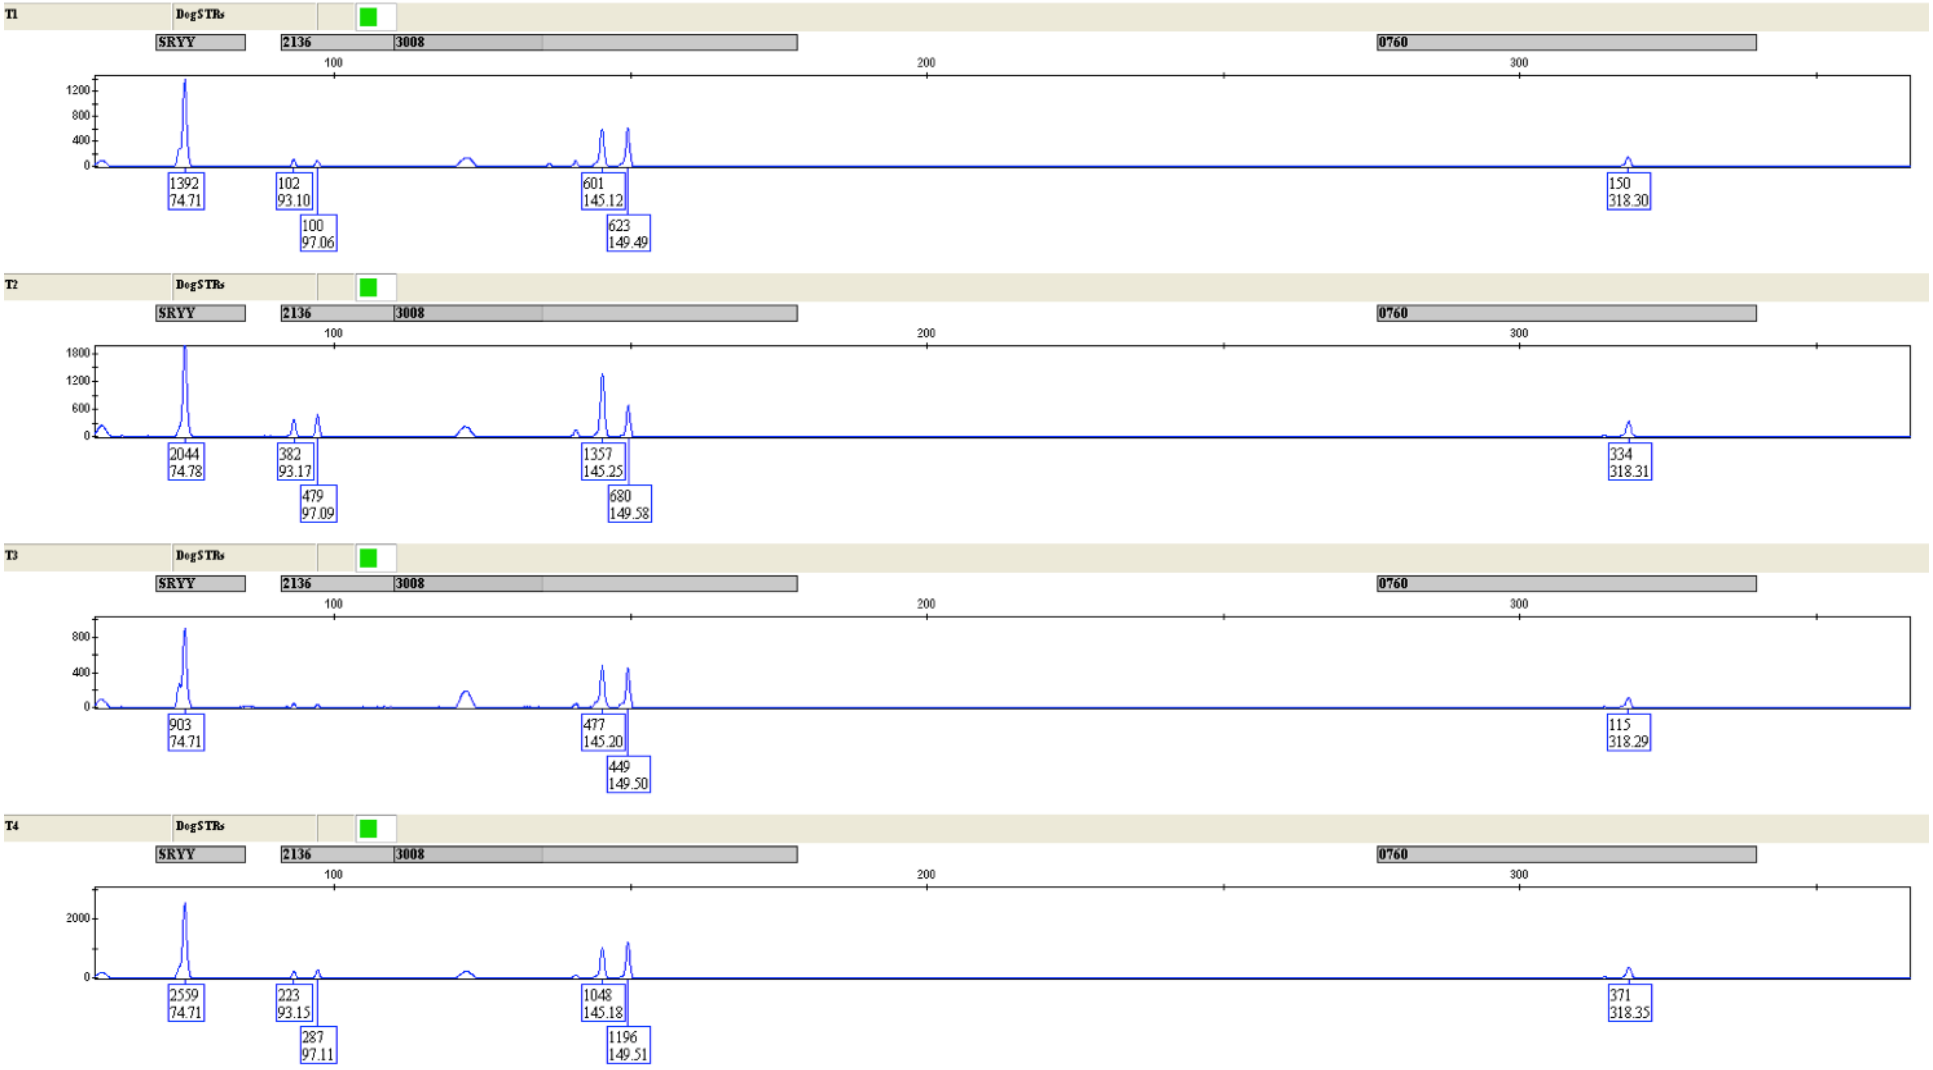

Figure 4.7 – Four chromatograms of nuclear canine DNA samples: shed undercoat hairs, amplified using QIAGEN® multiplex PCR kit and DogFiler loci at 31 cycles on a GeneAmp® System 9600 thermal cycler. Some allelic dropout and peak imbalance can be observed.

Short Communication

Successful direct amplification of nuclear markers from single dog hairs using DogFiler multiplex

We report on successful amplification of canine STR DNA profiles from single dog hairs. Dog hairs are commonly found on clothing or items of interest in forensic casework and may be crucial associative evidence if linked to an individual dog. We used direct amplification from these hairs to increase the DNA yield of the sample, as well as greatly reducing analysis time. Hairs from different somatic regions were used from several different dog breeds to amplify a selection of eight loci from the validated DogFiler multiplex. Naturally shed canine hairs were processed, with a mix of coarse topcoat (guard) hairs and thinner soft undercoat hairs. Multiple sections of single hairs were amplified in 5 mm segments to determine the viability of DNA recovery from the shaft of the hair. Single guard hairs were cut into 5 mm sections and added directly into a PCR tube. Undercoat hairs, which are very fine, were amplified together in a single tube (approximately ten small hairs). Coarse hairs were found to be the most successful in producing full DNA profiles at all eight loci, matching the corresponding reference profile for that dog.

It is estimated that 36–40% of Australian and American households own a domestic dog (*Canis lupus familiaris*) (http://www.acac.org.au/ACAC_Report_2010.html) [1]. This leads inevitably to a high level of contact between owners and their pets with the result that biological samples such as hair from dogs readily transferred from the dog to the owner or any person making contact with the dog. Shed dog hairs can therefore be an important piece of forensic evidence in investigations due to these transfer events.

Naturally shed hairs are the most commonly found hair types at crimes scenes. These telogen hairs have finished the growth cycle and lack the sheathing and root bulb, which typically contain high amounts of nuclear DNA required for successful profiling [2–4]. Mitochondrial DNA (mtDNA) has a much higher copy number within cells, which has made it the primary focus of DNA analysis involving the domestic dog [5–10]. Additionally animal DNA found at crime scenes can present degradation challenges caused by environmental exposure [11].

The use of mtDNA on dog hairs in casework can be associative evidence in linking a person to a place or item, however this can be complicated due to heteroplasmy within the mitochondrial DNA [7]. STR analysis of nuclear DNA has a higher discriminating power when it comes to cases with inbred or small populations [1, 12], and the introduction of miniSTRs has helped cope with issues surrounding degraded DNA [11].

The successful analysis of mtDNA from dog hairs has been reported [13], however only limited data [11, 14] or anagen hair data from one canine individual [15] exists for nuclear DNA STR analysis from dog hairs. Previous studies conducted on human hairs and human fingernails indicate the most likely source of directly amplified DNA is from nucleated cells or cell-free DNA on the surface of the hair or nail [3, 16, 17]. Studies implementing direct PCR methods on single fibres and touch DNA samples also indicate that the likely source of DNA, nucleated, or cell-free, is present on the surface of the sample [18–20]. Studies into direct PCR of human hairs showed an increased success rate compared to methods that use a DNA extraction step [3]. The aim of this study was to demonstrate the success rate of nuclear DNA recovery from single dog hairs that represent forensic casework scenarios thus allowing routine STR typing of a single shed hair. By implementing a direct PCR approach to processing dog hairs, the DNA yield can be greatly increased as DNA is

Table 1. Sample breakdown of the type of hair used per sample collection for each breed of canine

Dog breed	Sample collection BH ($n = 4$)	SH ($n = 4$)	CH ($n = 2$)
Golden Retriever 1	4 × U	3 × G 1 × M	2 × M
Golden Retriever 2	4 × U	4 × G	2 × M
German Shepherd	4 × U	3 × U 1 × M	2 × M
Kelpie x Staffy	4 × G	4 × G	2 × G
Bull Terrier	4 × G	4 × M	2 × G

Four brushed hair (BH) samples, four surface hair (SH) samples, and two clothing (CH) samples were collected from each canine. These are categorized as guard hair (G), undercoat hair (U), or a mixture of both (M).

not lost to the extraction process, as well as reducing the time and costs involved in processing evidence.

Preliminary studies conducted on anagen and telogen canine hairs, identified by microscopy, indicated that there was no observable difference in success rates between the two growth phases for obtaining DNA profiles using direct PCR (data not shown). Plucked hairs and shed hairs were provided with informed consent from one owner. All plucked hairs were identified to be anagen, and all shed hairs collected were identified to be telogen. Since casework samples are more likely to be shed hairs (telogen), the decision was made to only use this sample type in further testing. DAPI (4',6-diamidino-2-phenylindole) fluorescent staining was not considered for this study, as part of the aims is to minimize time and resources spent on processing the samples, as well as avoid the loss of DNA through washing or staining techniques.

Hair samples were collected from randomly selected domestic dogs (*Canis lupus familiaris*), comprising of three male and two female individuals. The breeds included two Golden Retrievers, a German Shepherd, Bull Terrier, and an Australian Kelpie × Staffy (Staffordshire). The owners of the canines provided informed consent in all cases. A buccal swab was collected from each of the dogs to act as reference and three hair collections: freshly brushed hair (BH) to represent freshly shed hairs; hair collected from surfaces such as couch or floor (SH) that represent hairs of unknown age; and hair collected from the owners' clothing (CH) to mimic typical case scenarios. Hairs ranged in length from approximately 2–7 cm. A total of 50 samples were processed, ten from each of the five dogs. The ten samples included four BH, four SH, and two CH from each dog, with hair types within these samples ranging from thick guard hairs to thin fluffy undercoat hairs, or a mixture of both, as outlined in Table 1. To maximize results, hairs collected within a single area or source were used in one reaction, with no discrimination of the type of hairs found within a collection; therefore some samples processed resulted in a mixture of undercoat and guard hairs. Hair samples were not treated in any manner prior to amplification in order to minimize the loss of DNA that may be present on the surface of the hair. Previous studies have demonstrated poor success rates in yielding sufficient autosomal DNA from human and canine hairs using standard extraction methods [2, 3, 11], and therefore were not attempted in this study.

As this is a proof-of-concept study, only eight of the 16 DogFiler loci were chosen, covering the complete range of fragment sizes from ~70 to 350 bp. This range and number of loci represent the size and ranges similar to that of human STR kits, such as Profiler Plus®, with sufficient loci to provide high powers of discrimination. The DogFiler assay [1] was favored over the Mini-DogFiler assay [11] for several reasons. The DogFiler multiplex was selected due to its similar design to human identification kits in regards to the range and size of loci included, as successful sampling of human hairs using direct PCR methods with standard human identification kits has been documented [3, 21]. Preliminary testing of DogFiler loci indicated no issues with amplification from single dog hairs. The DogFiler panel has also been integrated into forensic casework and accepted in courts across the United States [1]. Half-volume reactions were also utilized in the Mini-DogFiler study, but were not considered in this study due to the nature of direct PCR (sample placed directly into PCR fluid). The interest and focus was to determine the success of canine hairs with direct PCR methods by implementing standard procedures with validated protocols with little to no changes.

The eight chosen loci for this study included: VGL0760, VGL2136, VGL3008, SRY (Y), VGL1063, VGL2009, VGL1541, and VGL3235. The final primer concentrations in a 26 μL reaction was 0.19 μM for all primers, except for primer sets VGL2009 and VGL2136 where it was increased to 0.38 μM to help balance the multiplex. Primer sets were tagged with either VIC® or 6-FAM dye (Applied Biosystems).

Direct PCR was conducted by placing one or more hairs cut into 5 mm segments, prepared using sterile scissors and tweezers, into a 0.2 mL thin walled tube. Additionally, 13 μL of PCR master mix from the QIAGEN® multiplex PCR kit (Qiagen, Victoria, Australia) along with 10 μL of the primer mix was added to the PCR tube. A further 3 μL of sterile H_2O were added to make the final volume 26 μL. The amplification was conducted in a GeneAmp® System 9600 thermal cycler (Life Technologies). The PCR began with a 15 min activation step at 95°C, followed by 31 cycles of 30 s at 94°C, 90 s at 61°C, 1 min at 72°C, and a final extension for 30 min at 60°C. The PCR conditions follow the recommended conditions for the primers [1] and enzyme used by QIAGEN. There was no alteration to the methodology of amplification deliberately to ensure that the forensic science community could adopt the process readily.

DNA was isolated from buccal swabs using a QIAGEN® Mini kit (Qiagen, Victoria, Australia) following the manufacturer's protocol. The DNA was quantified using a Qubit® 2.0 Fluorometer (Life Technologies). From these extracts 1 ng was used in the PCR using the same conditions as for the hair samples.

Separation of the PCR products was performed on an ABI 3130*xl* Genetic Analyzer (Life Technologies) using POP-4™ polymer (Life Technologies). An aliquot of either 1 μL or 1 μL of a 1 in 30 dilution into H_2O of the PCR sample was added to

Table 2. Summary of DNA profiles obtained using eight loci from the DogFiler STR multiplex, using canine hair from five donors, total samples $n = 50$

Hair type	Number of samples			
	0 alleles	≤ 4 loci	≥ 5 loci	Full profile
Guard			7	16

Total comparable profiles			28	

a solution of 0.5 μL of ABI GeneScan-600 LIZ® Size Standard and 9.5 μL of Hi-Di™ Formamide (Life Technologies). Samples were then denatured at 95°C for 3 min. Electrophoresis was conducted at 3 kV with a 10 s injection. The data were analyzed using Genemapper® v3.2. (Life Technologies). The detection threshold was set at 50 relative fluorescence units (RFU).

A total of 50 dog hair samples from five individuals were amplified directly using eight loci from the validated DogFiler multiplex system (see Table 2). A full profile, comprising of all eight STR loci, was obtained from 17 samples (an example of which is seen in Fig. 1).

In human identification, a DNA profile consisting of five or more complete STR loci can be uploaded to the Australian National Criminal Investigation DNA Database (NCIDD), and is considered discriminating enough to minimize occurrences of adventitious matches. For this study, we have also considered all profiles of five or more complete STR loci to be "comparable" using population frequencies calculated from published data [1]. Comparable but not full profiles were obtained in an additional 11 samples.

There was an assumption that BH, being the most recently shed of the hair collections, would have the least degraded DNA and therefore give better profiles overall. However, there was no distinguishable pattern of success rate when comparing samples between the three different collection types (BH, SH, and CH). When comparing hair type, guard, and undercoat, there was a significantly higher success rate with guard hairs. When the 50 samples were categorized by the hair type, a link between success rates could be established. Guard hairs were present in 23 samples and all produced five or more complete loci, whereas all 19 undercoat hair samples failed to produce meaningful data. The thicker structure and nature of the guard hairs may allow for DNA to adhere easier to the surface than the thinner undercoat hairs. Eight samples contained a mixture of guard and undercoat hairs with 62.5% ($n = 5$) producing comparable profiles. It is not clear as to why only five of the eight mixed samples gave a comparable profile considering the 100% success rate of the guard hairs on their own. The hairs do not appear to dissolve or break down during the PCR process, however the thinner nature of the undercoat hairs may leave them more susceptible to breaking down during the PCR process, releasing some melanin, a known PCR inhibitor [22–24]. A second suggestion is that there simply

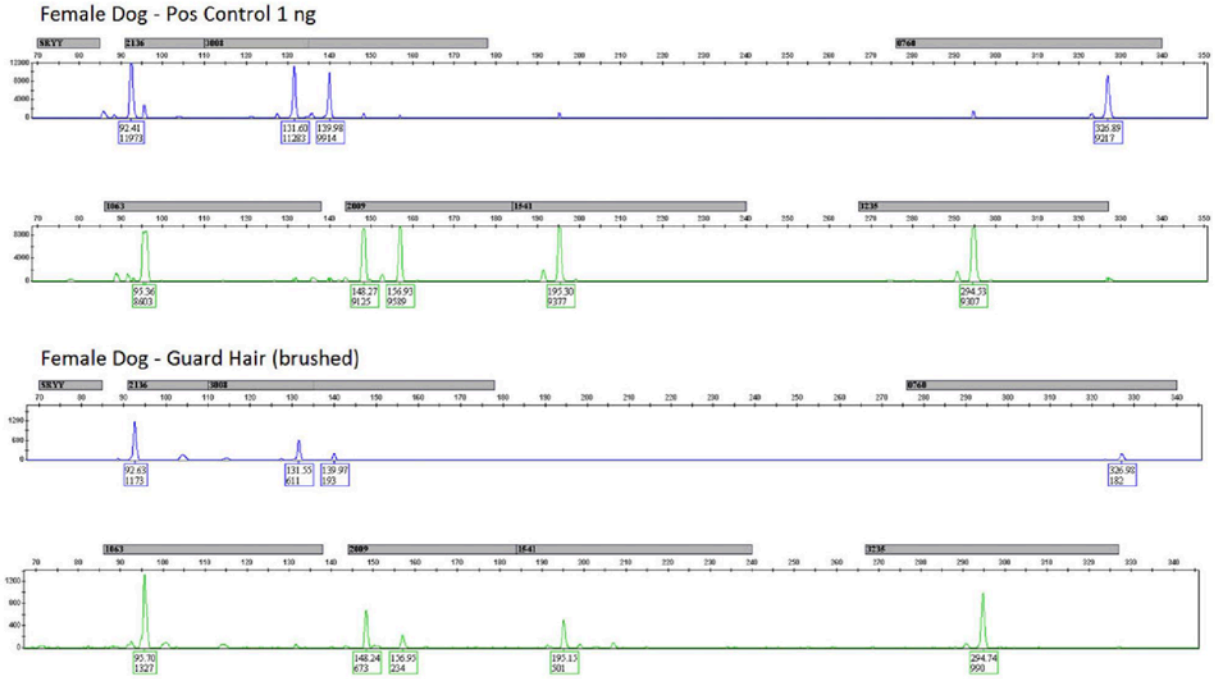

Figure 1. Chromatograms showing a positive nuclear DNA control sample compared to a single guard hair (brushed sample) from the same individual, exhibiting a matching full DNA profile.

may not be enough DNA present on the hairs of those particular samples processed. There was no discernible pattern to show that one breed of dog gave better profiles than another (data not shown). The proportion of hair types used in samples (guard, undercoat, or mixed), Table 1, were randomly selected and do not allow for equal comparison between dog breeds. In total, 56% of samples tested resulted in comparable profiles.

All DNA profiles obtained from hairs matched the DNA profile of the reference data of the donor dog. Allele sizes in this study were calculated using the fragment size obtained and published data [1] (http://www.cstl.nist.gov/strbase/dogSTRs.htm), as an allelic ladder was not available, and was not necessary to determine if the hair profiles and buccal swab profiles matched. Some profiles exhibited split allele peaks, typical of over amplification or inhibition during amplification. A dilution of the final PCR product reduced these affects as shown in previous studies [3] without causing allelic dropout. The average heterozygous peak balance (defined as the lower intensity peak divided by the higher intensity peak) of all direct amplification samples was observed to be 73.4%. Allelic dropout occurred in the expected range (larger loci) and drop-in was not observed in any sample. The average RFU value was 1819 for all samples that generated data.

By implementing a direct PCR approach to canine hair samples, we have demonstrated that nuclear STR profiles can be generated routinely from a single guard hair even if the time since being shed is unknown. There is a reduction in time and costs by omitting the extraction step and there is no loss of DNA during the extraction process allowing single hairs to be processed successfully. We make the recommendation of only processing guard hairs for direct PCR due to the higher success rate of obtaining comparable data for statistical analysis.

4.4 Applications

4.4.1 Casework

Flinders University DNA Laboratory was asked by FSSA and SAPOL to analyse DNA samples obtained from a latex glove and determine if canine DNA was present and if that canine DNA profile matched a DNA extraction from exhumed canine bones (Case 2 and Case 3). The DNA results were presented as evidence at *R v Lowe*, a decade old attempted murder case. This section contains copies of: the joint statement of Renée Blackie and Adrian Linacre; the PCR set-up conditions; the DNA profiles obtained from the case evidence and five positive control samples (Figures 4.8 – 4.12); the calculated allele frequencies; and a news report of the final case ruling.

In a separate case, Flinders University DNA Laboratory was asked by FSSA and SAPOL to analyse a DNA extract and determine if canine DNA was present (Case 4).

Case 2

Determining the presence of canine DNA in an extraction obtained from a glove

STATEMENT OF WITNESS

Statement of:	Renée Ottens	Adrian Linacre
Occupation:	Forensic Scientist	SA Justice Chair in Forensic Science
Address:	Flinders University Adelaide, SA	Flinders University Adelaide, SA

Date:

This statement (consisting of 3 pages) each signed by us, is true to the best of our knowledge and belief and we make it knowing that, if it is tendered in evidence, we shall be liable to prosecution if we have wilfully stated anything that we know to be false or do not believe to be true.

Instruction

We were instructed by Dr Andrew Donnelly to determine if DNA from a dog was present within two samples.

Items Received

Samples 173-53.A and 173-53 were received from Dr Donnelly on 3 April at Forensic Science South Australia. The samples were transferred to the Forensic DNA Laboratory at Flinders University where the analyses were performed.

Results

A full canine specific DNA profile (8 loci from the DogFiler multiplex) was generated from sample 173.53.A and 173.53. The DNA profiles were the same. The DNA data indicate that the DNA came from a male dog.

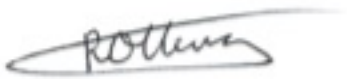
Conclusion

It is our conclusion that:

DNA from a dog (*Canis lupus familiaris*), or another member of the Canis genus, was present with both samples provided.

The data are as expected if DNA from the same male dog was present in both samples. If the DNA came from two different dogs then the DNA profiles must match by chance. It is not possible to state this chance event without access to a relevant database of DNA types within the local dog population.

Signed



Renée Ottens, BSc. (Hons)

Signed

Adrian Linacre, B.Sc. (Hons), D.Phil.

APPENDIX: CANINE SHORT TANDEM REPEAT TYPING

The DNA profiling performed in this case is similar to that used in human identification and examines short tandem repeat markers (STRs). The STR markers used in case were published by Developmental validation of DogFiler, a novel multiplex for canine DNA profiling in forensic casework (*Wictum et al Forensic Science International: Genetics, 2013, 7:1 82-91*)

The DNA markers chosen have been shown to be the same for if the DNA test is performed on saliva, hair or blood.

The test used is designed to work on the domestic dog (*Canis lupus familiaris*). The markers will generate a DNA profile from DNA originated from other members of the dog genus including the grey wolf (*Canis lupus*) and the dingo (*Canis lupus dingo*).

As well as STR markers, a gender test is included in the test to indicate if the DNA came from a male or female dog.

The DNA markers are known to be highly variable even within breeds. When two different samples give the same DNA profile then these are the data expected if the DNA came from the same dog. It is possible to estimate the probability that the two DNA samples come from the same dog if there is a suitable reference database of the frequencies of the DNA types in the local dog population.

End of statement

Case 3

Determining if the canine DNA from Case 2 matches bone DNA from exhumed pet

STATEMENT OF WITNESS

Statement of:	Renée Blackie	Adrian Linacre
Occupation:	Forensic Scientist	SA Justice Chair in Forensic Science
Address:	Flinders University	Flinders University
	Adelaide, SA	Adelaide, SA

Date: 20th May, 2015

This statement (consisting of 4 pages) each signed by us, is true to the best of our knowledge and belief and we make it knowing that, if it is tendered in evidence, we shall be liable to prosecution if we have wilfully stated anything that we know to be false or do not believe to be true.

Statement

This statement is supplemental to or statement dated 2nd May 2014.

Instruction

We were instructed by Dr Andrew Donnelly of Forensic Science SA to generate a canine DNA profile from sample taken that we understand was taken from the bone of a deceased dog. If a DNA profile can be generated from this sample we were instructed to compare this DNA profile to that obtained from a sample taken from a glove (as detailed in our previous statement dated 2nd May 2014). If the profiles matched then an opinion should be provided as to the probability that the two samples come from the same dog compared to coming from two different and unrelated dogs.

It is assumed that the information provided is accurate. If new information is provided we are willing to alter our opinions.

Items Received

Samples 173_89.1A and 173_89.2A were received at the Forensic DNA Laboratory at Flinders University on 9th July from Sherryn Ciavaglia of FSSA. It is understood that these two DNA extracts had been obtained from a bone sample taken from a deceased dog. Extract 173_89.1A was given the code bone_1 and extract 173_89.2A given the code bone_2.

Results

Canine DNA testing was performed in the forensic DNA laboratory at Flinders University. Canine DNA profiles were generated from bone_1 and bone_2 (using the test described in the Appendix). Both canine DNA profiles from the bone sample were incomplete but come from a male dog. An incomplete DNA profile is typical of insufficient DNA present within the bone samples to that is required to generate a complete profile.

The canine DNA profiles obtained from bone extracts bone_1 and bone_2 were found to match each other as would be expected. The canine DNA profiles from bone_1 and bone_2 were found to match the canine DNA profile obtained from the sample taken from a glove (sample 173-53).

These are the DNA data expected if bone_1 and the DNA extract from the glove sample 173-53 came from the same male dog. If these two samples come from different dogs then they must match by chance. It is estimated that the chance of obtaining matching canine DNA profiles if the DNA from sample 173-53 came from a different and unrelated male dog as the bone extract bone_1 is in the order of 1 in 500 thousand.

These are the DNA data expected if bone sample bone_2 and glove sample 173-53 came from the same dog. If these two samples come from a different dog then they must match by chance. It is estimated that the chance of obtaining matching canine DNA profiles if the DNA from sample 173-53 came from a different and unrelated male dog as the DNA sample bone_2 is in the order of 1 in 500 thousand.

Conclusion

It is our conclusion that there is very strong support for the premise that the DNA taken from the glove came from the same dog as the DNA taken from a bone sample.

Renée Blackie, BSc. (Hons)

Signed

Adrian Linacre, B.Sc. (Hons), D.Phil.

APPENDIX: CANINE SHORT TANDEM REPEAT TYPING

The DNA profiling performed in this case is similar to that used in human identification and examines hypervariable regions in the dog genome called short tandem repeat markers (STRs). The STR markers used in case were published in the scientific paper 'Developmental validation of DogFiler, a novel multiplex for canine DNA profiling in forensic casework' (*Wictum et al Forensic Science International: Genetics, 2013, 7:1 82-91*).

The test used examines 8 hypervariable STR loci. As well as STR markers, a gender test is included in the test to indicate if the DNA came from a male or female dog.

The DNA markers chosen have been shown to be the same if the DNA test is performed on saliva, hair bone or blood.

The test used is designed to work on the domestic dog (*Canis lupus familiaris*). The markers will generate a DNA profile from DNA originated from other members of the Canus genus including the grey wolf (*Canis lupus*) and the dingo (*Canis lupus dingo*).

The DNA markers are known to be highly variable even within breeds. When two different samples give the same DNA profile then these are the data expected if the DNA came from the same dog. If the DNA samples come from two different dogs then the DNA profiles must match by chance. It is possible to estimate the probability that the two DNA samples come from the same dog compared to two different dogs if there is a suitable reference database of the frequencies of the DNA types in the local dog population. Allele frequencies were obtained from Wictum et al Forensic Science International: Genetics, 2013, 7:1 82-91 and a kinship factor of 0.05 was applied. In the case of an absent allele the 2p rule was applied.

News Report: Final Ruling

NEWS

Jury finds Nicholas Wayne Lowe guilty of attempted murder after attack with metal pole

By court reporter James Hancock

Updated Thu 30 Jul 2015, 5:25pm

A man jailed for stealing more than $1 million from the Victims of Crime Compensation Fund has been convicted of attempted murder.

The Supreme Court heard Nicholas Wayne Lowe, 33, attacked Nanette Clarke with a metal pole in her Port Lincoln home in August 2003.

A publication ban on Lowe's identity was automatically lifted after the jury delivered its unanimous guilty verdict.

It is Lowe's second trial on the current matter after a jury was unable to reach a verdict in June last year.

Lowe is already serving 10 years in jail for stealing from the compensation fund when he was a clerk in the Crown Solicitors office.

He made bogus compensation claims for family and friends and kept nearly half of the money for himself over a four-year period until his arrest in September 2012.

During the trial, Prosecutor Peter Longson told the jury that Lowe attacked Ms Clarke with a metal pole, causing serious brain damage.

He said she spent five weeks in hospital and still suffers memory problems.

"It was a year before she returned to full-time work or could drive a car," he said.

Mr Longson said Lowe's DNA profile was found on several objects at the crime scene, including a balaclava.

He said Ms Clarke's partner and son returned home to find her lying in her car.

"[She was found] unconscious, lying face first into the passenger foot well with the rest of her body and legs draped over and between the front seats," Mr Longson said.

"She was exposed from the waist down, she was just wearing a shirt on top, which is what she wore to bed."

He said there was a very large amount of blood in the house, with two significant areas around the dining table.

"There was a drag mark of blood that ran for three-and-a-half metres ... that led from the second area towards the garage door."

Lowe had been going out with the daughter of Ms Clarke's partner.

The case returns to court next week to address sentencing matters.

News Report: Final Sentencing

NEWS

Nicholas Wayne Lowe jailed for 20 years for attempted murder after attack with metal pole

By court reporter James Hancock

Updated Mon 14 Sep 2015, 12:20pm

An Adelaide man jailed for 10 years for stealing from a victims of crime fund has had 20 years added to his sentence for attempting to murder a Port Lincoln woman.

Nicholas Wayne Lowe attacked Nanette Clarke with a metal pole in her home on South Australia's Eyre Peninsula in August 2003.

She almost died from the attack.

The Supreme Court heard her partner and son returned home early from a fishing trip because of bad weather to find her lying in the foot well of her car.

Ms Clarke suffered a brain injury in the attack and still has problems with her memory, hearing loss and sense of taste and smell.

Lowe, 33, was not arrested for the crime until 2012, after DNA provided following his arrest on the victims of crime case was matched to the scene of the attack.

A jury unanimously found him guilty of attempted murder in July.

The judge set a new head sentence of 30 years for both crimes, with a non-parole period of 20 years.

Outside court, Ms Clarke welcomed the jail term.

"We are really very happy with the sentencing and look very much forward to just moving on and having some normality in our lives now," she said.

Justice Malcolm Blue described the attack as a "particularly serious version of attempted murder".

He said the motive for the "premeditated offence" was unknown.

Victim was shocked by Lowe's arrest

Lowe was dating the daughter of Ms Clarke's partner at the time of the attack.

The court was told Lowe was not considered a suspect by police.

Ms Clarke spoke in court of her shock at learning in September 2012 of Lowe's arrest for her bashing.

He had also been arrested for stealing more than $1 million from the Victims of Crime Compensation Fund.

Lowe stole the victims of crime money while working as a clerk in the Crown Solicitors Office.

Last December, Lowe was jailed for 10 years with a non-parole period of seven years for 26 counts of dishonestly dealing with documents.

Lowe will now also serve 20 years for Clarke's attempted murder, cumulative on the 10 years he is currently doing for the prior offending.

The judge said Lowe, who is married with a two-year-old son, is receiving support from family whilst in jail.

Case 4

Determining the presence of canine DNA in a sexual assault allegation

STATEMENT OF WITNESS

Statement of:	Renée Ottens	Adrian Linacre
Occupation:	Forensic Scientist	SA Justice Chair in Forensic Science
Address:	Flinders University Adelaide, SA	Flinders University Adelaide, SA

Date: 3rd July 2014

This statement (consisting of 3 pages) each signed by us, is true to the best of our knowledge and belief and we make it knowing that, if it is tendered in evidence, we shall be liable to prosecution if we have wilfully stated anything that we know to be false or do not believe to be true.

Instruction

We were instructed by Mark Webster of Forensic Science South Australia (FSSA) to determine if DNA from a dog was present within a sample provided.

Items Received

Sample 565-2B was received into the Forensic DNA Laboratory at Flinders University from Sherryn Ciavaglia of FSSA on 4th June 2014. The sample consisted on one screw top tube containing a small amount of colourless fluid. The sample was stored securely at the Forensic DNA Laboratory prior to analysis.

Results

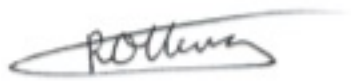
A full canine specific DNA profile was generated from sample 565-2.B. The DNA data indicate that the DNA came from a male dog.

Conclusion

It is our conclusion that:

DNA from a male dog (*Canis lupus familiaris*), or another member of the Canis genus, was present in the sample provided.

Signed



Renée Ottens, BSc. (Hons)

Signed

Adrian Linacre, B.Sc. (Hons), D.Phil.

APPENDIX: CANINE SHORT TANDEM REPEAT TYPING

The DNA profiling performed in this case is similar to that used in human identification and examines short tandem repeat markers (STRs). The STR markers used in case were published by Developmental validation of DogFiler, a novel multiplex for canine DNA profiling in forensic casework (*Wictum et al Forensic Science International: Genetics, 2013, 7:1 82-91*)

The DNA markers chosen have been shown to be the same for if the DNA test is performed on saliva, hair or blood.

The test used is designed to work on the domestic dog (*Canis lupus familiaris*). The markers will generate a DNA profile from DNA originated from other members of the dog genus including the grey wolf (*Canis lupus*) and the dingo (*Canis lupus dingo*).

As well as STR markers, a gender test is included in the test to indicates with the DNA came from a male or female dog.

The DNA markers are known to be highly variable even within breeds. When two different samples give the same DNA profile then these are the data expected if the DNA came from the same dog. It is possible to estimate the probability that the two DNA samples come from the same dog if there is a suitable reference database of the frequencies of the DNA types in the local dog population.

End of statement

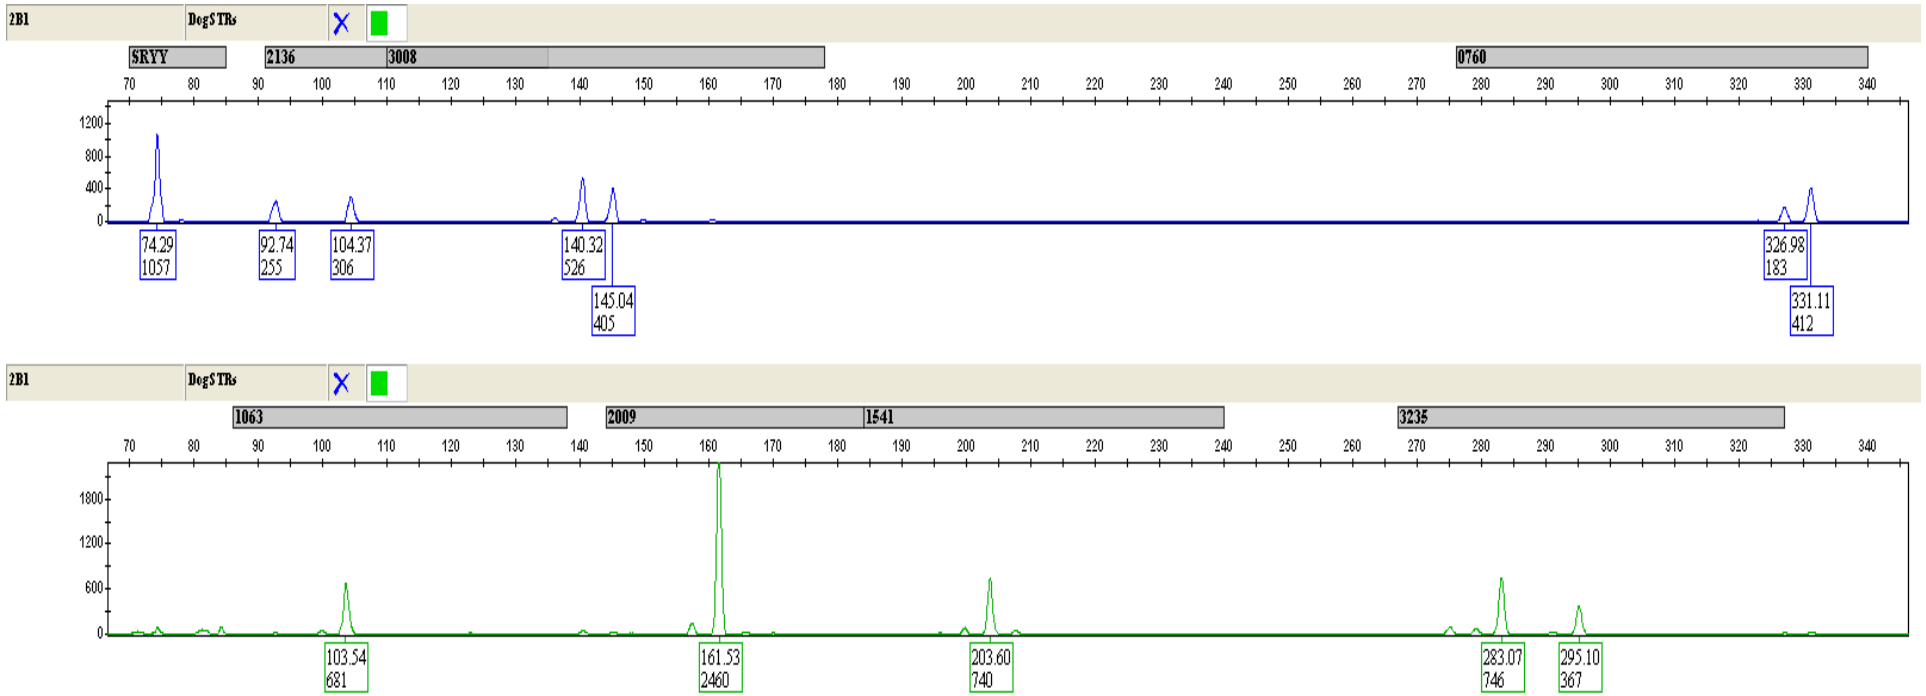


Figure 4.13 – Chromatogram of nuclear canine DNA from sample 565-2.B, amplified using QIAGEN® multiplex PCR kit and DogFiler loci at 31 cycles on a GeneAmp® System 9700 thermal cycler.

4.4.2 Cold Case Potential

The first time animal DNA was accepted as evidence in court was for the 1994 murder of Shirley Duguay, where the now infamous cat Snowball's hair implicated the murder suspect [6]. A man's leather jacket was found shortly after the discovery of the victim's bloodied abandoned vehicle. The jacket was also stained with the victim's blood and had many white domestic cat hairs inside the lining. The suspect, the victim's estranged common-law husband, lived with his parents and a white shorthaired pet cat named Snowball. One of the 27 hairs from the jacket contained enough root material for extraction and amplification of ten feline dinucleotide STR loci [7]. The results concluded that the hairs found on the coat came from Snowball, and were presented and admitted to the Supreme Court of Prince Edward Island. The suspect was found guilty of second-degree murder in July of 1996.

Since this landmark case, animal DNA amplified from hairs, faeces, urine stains, tissue samples or blood has been submitted as evidence in cases ranging from burglary, to animal abuse, sexual assaults and murder [8-16]. Although the use of animal DNA in criminal casework has continued since 1996, it is still relatively new to many countries. The first time feline DNA was submitted as evidence in a UK criminal trial was in 2012, where David Hilder was convicted for manslaughter after hairs from his pet cat were discovered on the dismembered torso of David Guy. Many cases, such as the one just mentioned, have focused on the use of mitochondrial DNA due to their high copy number and higher chance of profiling success. A shift to nuclear DNA genotyping has only emerged more recently as techniques become more sensitive [5, 17].

Direct PCR using human (*section 3.2*) and canine (*section 4.3*) hairs has shown a tremendous improvement on current methods in obtaining valuable nuclear DNA information. Both studies tested hairs of unknown age [18, 19], providing hope for cold cases where single hairs may not have been processed due to low success rates. Criminal investigations from the past, prior to routine DNA sampling, have a higher chance of human DNA contamination due to a lack of knowledge about DNA transference and DNA collection methods. Animal DNA contamination is a lot less likely to occur, making it an ideal target source for direct PCR. An unsolved Australian murder case mimics this scenario; Gerard Ross, aged 11, was abducted in October of 1997 and his body was found at a nearby pine plantation two weeks later [20]. Throughout the investigation, those collecting evidence had unfortunately contaminated it, thus making resampling and analysing with new techniques impossible. The discovery of dog hairs on his body and clothing gave hope to the investigation, as the family did not own a dog. It is unclear to what extent the dog hairs were tested and analysed, if at all.

4.5 Concluding Remarks

Similarly to human hairs, canine hairs can be successfully amplified using direct PCR, with both sets of data supporting the theory of nuclear and cell-free DNA being present on the surface of the hair, as well as in the root material. It can therefore be assumed that similar results would be achievable using hair from other animal types, such as the domestic cat. Criminal investigators all over the world are recognising the power of animal DNA in criminal casework, particularly where there may be no other linking or DNA evidence. Forensic scientists are now pooling their research data on animal genotypes, creating worldwide databases for domestic dogs and cats, ensuring that population frequency statistics can be applied in the same way human DNA is analysed [21-27]. Direct PCR of animal hairs can be a powerful tool in future criminal investigations, especially those of a time sensitive nature, as the analysis process is shortened without compromising the quality of the results.

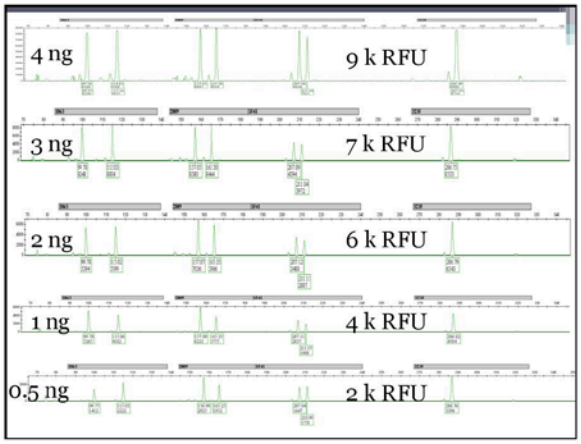
DogFiler

- No Ladder
  - Must run positive control + hair sample each time
- Create Panel + Bin Sets
- Optimal DNA Concentrations unknown
  - Human DNA 23 chromosomal pairs = 1 ng
  - Canine DNA 39 chromosomal pairs = ?
- Primer Concentrations unknown
  - Not listed in papers
- PCR:

	31 cycles			
1 min	30 s	30 s	1min	30 min
95°	95°	62°	72°	72°

Limit of Detection

- What can be detected by DogFiler?
- Two dogs – 1 male, 1 female
  - 4, 3, 2, 1, 0.5 ng of DNA
  - Repeated twice each
  - 2 - 3 ng best results – balanced peaks
  - Still strong detection at 0.5 ng



Canine Hair Types

- Telogen & Anagen
- Top Coat/ Guard hairs – thick, coarse
- Under Coat – thin, fluffy
- What is more likely to be seen in a casework scenario?

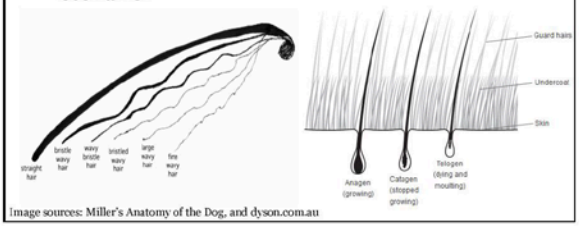


Image sources: Miller's Anatomy of the Dog, and dyson.com.au

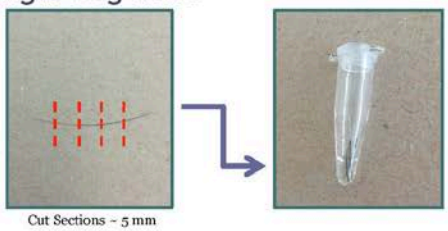
Single Dog Hairs

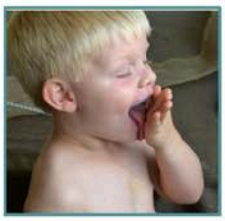


Cut Sections ~ 5 mm

Theory: Nuclear DNA present on surface of hair
- Nucleated cells or cell free DNA

Source: Skin secretion

Canine Vs Human Hygiene



Canine Results

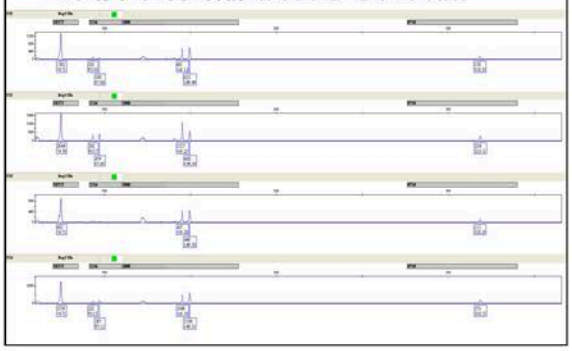
- Telogen (guard hair)

- Anagen (guard hair)

- Pos

Canine Results

- Tufts of under coat - several small hairs in one tube



Prelim Experiment

- Results showed no difference between anagen and telogen hairs
- Telogen (shed) hairs would best represent casework scenario
- Not necessary to forcefully take anagen hairs from dogs

- Note: Canine telogen hair performed better than human telogen hair

Experiment

- 5 dogs of random breeds
  - 3 male, 2 female
- Hair samples and buccal swabs collected (ref)
  - Hair freshly brushed **x 4**
  - Hair from surfaces in the house (floor, couch) **x 4**
  - Hair from clothing of owner **x 2**

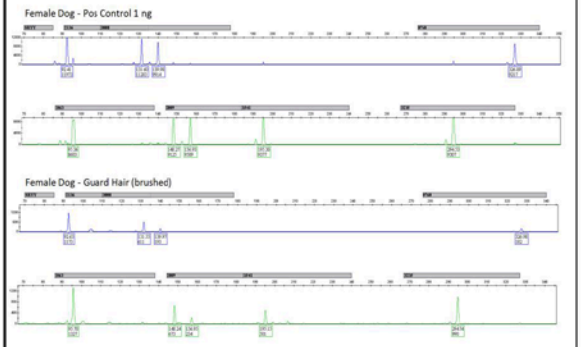
  Range of guard and undercoat hairs
- 50 samples in total

Summary of Results

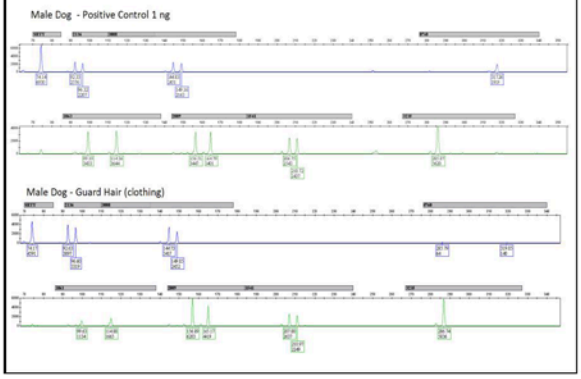
Arranged by hair type instead of location collected

Direct Sample Type	DNA Recovered/ Sample Number	Percentage Recovered
Undercoat Hairs	2/18	11 %
Guard Hairs	23/23	100 %
Mixed	6/9	67 %
Total Recovery	31/50	62%

Direct & Pos Control



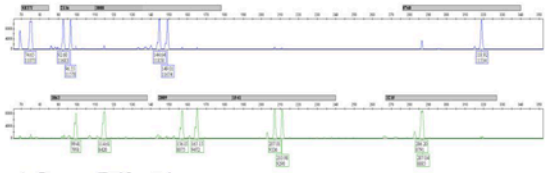
Direct & Pos Control



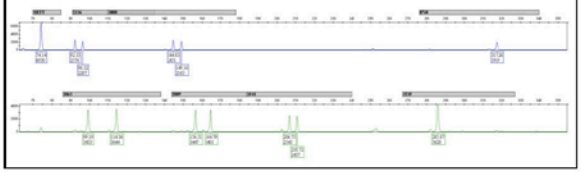
Inhibition

- Too much DNA can cause:
  - Overloaded Samples
    - Split peaks, noisy baseline, pull-up
- Overcome with:
  - PCR product dilution on gel electrophoresis
  - Additional enzyme in PCR set up

Before Dilution



After Dilution



Summary

- Extraction process circumvented
  - DNA not lost via wash steps or tube changes
  - Greater DNA yield
- Dog hairs are currently not processed for DNA due to low success rate
  - Guard hairs most successful in obtaining DNA
- Cost effective and time saving
- Already validated Canine STRs for identification
  - Easy & quick implementation in forensic labs

Successful direct amplification of nuclear markers using single dog hairs with eight DogFiler loci

Renée Ottens[1], Adrian Linacre[2]

1 School of Biological Science, Flinders University, Bedford Park, SA, Australia, renee.ottens@flinders.edu.au

2 School of Biological Science, Flinders University, Bedford Park, SA, Australia, adrian.linacre@flinders.edu.au

We report on successful amplification of canine STR DNA profiles from single dog hairs. Dog hairs are commonly found on clothing or items of interest in forensic casework and may be crucial associative evidence if linked to an individual dog. We used direct amplification from these hairs to increase the sensitivity and DNA yield of the sample, as well as reducing analysis time. Hairs from different somatic regions were used from several different dog breeds to amplify a selection of eight loci from the validated DogFiler multiplex. Both anagen and telogen hairs were processed, with a mix of coarse topcoat hairs and thinner soft undercoat hairs. For single coarse hairs, approximately 5 mm from the proximal tip was added directly into a PCR tube. Multiple sections of a single hair were amplified in 5 mm segments to determine the viability of DNA recovery from the shaft of the hair. Undercoat hairs, which are very fine, were amplified together in a single tube (approximately 10 small hairs). Each hair type and fragment consistently produced a full DNA profile using all eight loci that matched the corresponding reference profile for that dog.

Direct PCR from Human Fingernails

5.1 Preface

From the previous direct PCR studies on canine and human hair, it can be inferred that the presence of nucleated cells or cell-free DNA would also be available on the surface of fingernails. Like hair, nails are made from keratin and have the propensity to maintain DNA on the surface, from skin secretion or sebum as the nail grows, even when exposed to extreme environmental conditions [1, 2]. Unlike hair however, fingernails are more likely to pick up PCR inhibitors such as dirt, nail polish, or cleaning chemicals through regular daily activities and exposure to the environment.

Fingernails can be used to target different sources of DNA; a victim may have collected foreign DNA under their fingernails during an attack or struggle with a perpetrator, in which case the victim's nails may either be collected or scraped underneath to collect any tissue or DNA material present [3-6]. Alternatively, fingernails have been used in victim identification [7, 8], where whole nails are collected and processed as a non-invasive method to obtain DNA information about the victim. Similarly, many difficulties arise during mass disaster victim identification [9, 10], particularly with sample collection and storage [11], making fingernails an ideal source of DNA in these scenarios.

The method for analysing DNA from fingernails varies greatly between laboratories; fingernails may be cut and pooled into one extraction, swabbed or scraped [1, 4-6, 12]. The collection method would then affect the extraction method chosen, and thus the success rate of obtaining important DNA information. Direct PCR has the potential to greatly decrease the time taken to process fingernail samples, as well as increasing the likelihood of consistently obtaining important DNA information. The following sections investigate the application of human fingernails substrate for direct PCR (*5.2*), and the future implementation and use of direct PCR in mass disaster investigations (*5.3*).

TECHNICAL REPORT

DNA profiles from fingernails using direct PCR

Renée Ottens · Duncan Taylor · Adrian Linacre

Accepted: 9 October 2014 / Published online: 13 November 2014

Abstract We report on the successful routine amplification of DNA profiles from small sections of fingernails using direct PCR. The data are from 40 nail clippings from eight donors where approximately 4 mm^2 of nail is added directly to the PCR. The NGM^{TM} kit was used that amplifies 15 STR loci plus amelogenin. No increase in cycle number was used and no enrichment of the PCR products was performed. Full DNA profiles were observed in 17 of the 40 profiles with 21 generating partial DNA profiles. The process omits the DNA extraction process, and hence there is no opportunity to quantify the DNA prior to amplifying the STRs, but by not performing a DNA extraction step, the amount of DNA available for PCR is maximized. Single source DNA profiles were observed in 29 of the 38 profiles obtained. The source of the DNA is assumed to be adhering to the underside of the nail. This simple method offers a significant reduction in time to generate DNA profiles from nail clippings, such as those taken from victims of mass disasters, and should be included into a forensic process relatively easily as it requires no change to manufacturer's instructions for amplification.

Introduction

We report on a highly successful method of direct amplification of DNA from human fingernail clippings. Fingernail clippings can be a source of human identification with the DNA preserved within the keratin structure of the nail. Isolation of DNA from the fingernail normally requires incubation of 24 h or more, until the nail has completely digested, in a buffer containing proteinase K and dithiothreitol (DTT). Direct PCR of samples has gained much interest in a forensic context due to the potential saving in time [1–4], increase in sensitivity and minimizing of steps open to error or contamination [5]. Much of the focus has been on direct amplification from a body fluid stain [6] with an emphasis also on the speed of the DNA typing [7] and the types of DNA polymerase used. Previous reports have illustrated the potential benefit of direct amplification from fibers [5], hair [8, 9], and touch DNA [10, 11]. The potential to generate a profile from fingernail clippings is dependent on the presence of nucleated cells or cell free DNA present on the surface of the nail from skin secretion or sebum. The aim of this study was to develop a simple, operational method that could be used routinely in forensic science casework with no special laboratory requirements, reducing the time taken to process evidence that provides a greater DNA profiling success rate than standard extraction method [12].

Materials and methods

Samples

Fingernail clippings were collected from both male and female donors working in the forensic DNA laboratory

at Flinders University. Confirmed consent was provided in all cases and clearance was provided by the Southern Adelaide Clinical Human Research Ethics Committee. Each donor was asked to provide a clipping from each finger after showering or washing their hands. A total of 40 fingernail clippings from eight donors were analyzed. DNA extracts from buccal swabs were also provided as references of donors. Fingernail clippings were not treated in any manner prior to amplification.

Direct PCR amplification and conditions

Direct PCR was conducted by using a nail cutting approximately 2 mm × 2 mm in size, prepared using sterile scissors and tweezers. A single fragment was placed into a 0.2 mL thin walled tube containing 10 µL of PCR master mix from the AmpFℓSTR® NGM™ kit (Life Technologies, VIC, Australia) along with 5 µL of the primer mix and 1 µL of AmpliTaq Gold® DNA polymerase. A further 9 µL of sterile H_2O were added to make the final volume 25 µL. The amplification was conducted in a GeneAmp® System 9600 thermal cycler (Life Technologies) using the manufacturer's recommended conditions. The standard 29 cycles was used for all reactions. There was no alteration to the methodology of amplification deliberately to ensure that the process could be adopted readily by the forensic science community. The NGM™ kit amplifies 15 STR loci plus the amelogenin locus.

Analysis of buccal swab

DNA was isolated from buccal swabs using a Qiagen Mini kit (Qiagen, VIC, Australia) following the manufacturer's protocol. The DNA was quantified using a Qubit® 2.0 Fluorometer (Life Technologies). From these extracts 1 ng of DNA was used in the PCR using the same conditions as for the direct fingernails samples.

DNA extraction comparison

Two nail fragments from each donor, measuring approximately the same size as was used in the direct PCR method (2 mm × 2 mm), were extracted using a Qiagen Mini Kit. A total of 16 extractions were performed following the manufacturer's protocol. The fragments were incubated for 24 h and eluted in a final volume of 50 µL. The DNA was quantified using a Qubit® 2.0 Fluorometer (Life Technologies). From these extracts 1 ng, where possible, or 10 µL of DNA extract if the DNA was at a sub-optimal concentration, was used in the PCR using the same conditions as for the direct fingernail samples.

Capillary electrophoresis

Capillary electrophoresis was performed on an ABI 3130*xl* Genetic Analyser (Life Technologies) using POP-4™ polymer (Life Technologies). An aliquot of either 1 µL, or 1 µL of a 1 in 30 dilution into H_2O, of the PCR sample was added to a solution of 0.5 µL of ABI GeneScan-600 LIZ® Size Standard and 9.5 µL of Hi-Di™ Formamide (Life Technologies). Samples were then denatured at 95 °C for 3 min. Electrophoresis was conducted at 3 kV with a 10 s injection. The data were analyzed using Genemapper® v3.2 (Life Technologies). The detection threshold was set at 50 relative fluorescence units (RFU).

Results and discussion

A total of 40 fingernail clippings from eight individuals were amplified directly using the NGM™ kit and the data analyzed (see Table 1). A full profile, comprising all 15 STR loci and the amelogenin locus, was obtained from 17 samples (an example of which is seen in Fig. 1). Profiles resulting in allelic drop-out, from the major component, of two alleles or less (almost complete NGM™ DNA profile) occurred in ten samples. Eleven samples produced a DNA profile of five or more complete STR loci (partial profile) that could be uploaded to the Australian National Criminal DNA Database (NCIDD). Only two samples from the 40 tested generated profiles of seven alleles or less.

Seven profiles exhibited split allele peaks, typical of over amplification or inhibition during amplification. A dilution of the final PCR product reduced these affects as shown in previous studies [8] without causing allelic dropout. The average heterozygous peak balance (defined as the lower intensity peak divided by the higher intensity peak) of all direct amplification samples was observed to be 79.9 %. Dropout occurred in the expected range (larger loci). The heterozygous peak balance for the extracted samples was overall lower at 68.9 %, with 75 % of samples exhibiting split peaks and pull-up that could not be reduced without losing alleles at the larger loci.

Additional alleles from a minor contributor were observed in nine (22.5 %) samples (an example of which is seen in Fig. 2). Six samples contained a single minor allele, and the remaining three samples contained between three and six minor alleles. The minor alleles were all consistent with a cohabiting partner of the donor. These figures are consistent with previous control sample studies, showing foreign DNA contribution to fingernail samples to be between 13 and 23 % [12]. By contrast, the extracted samples in this study showed a much larger foreign DNA contribution at 81.2 %, where the major or minor component could not be distinguished in 61.5 % of those samples

Table 1 Summary of DNA profiles obtained using the NGM ™ STR kit from fingernail clippings 2 mm × 2 mm in size from eight donors, total samples $n = 40$

Full profile	Almost full profile	Partial profile (uploadable)	Incomplete profile	Foreign DNA detected	
15 complete loci	Drop-out of ≤ 2 alleles	≥5 complete loci	≤4 complete loci	Single allele	Multiple alleles (≤6 alleles)
42.5 % ($n = 17$)	25 % ($n = 10$)	27.5 % ($n = 11$)	5 % ($n = 2$)	15 % ($n = 6$)	7.5 % ($n = 3$)
Profiles uploadable to NCIDD (%)			Total percentage of profiles containing foreign DNA		
95			22.5		

Number of samples where foreign DNA was detected is also shown

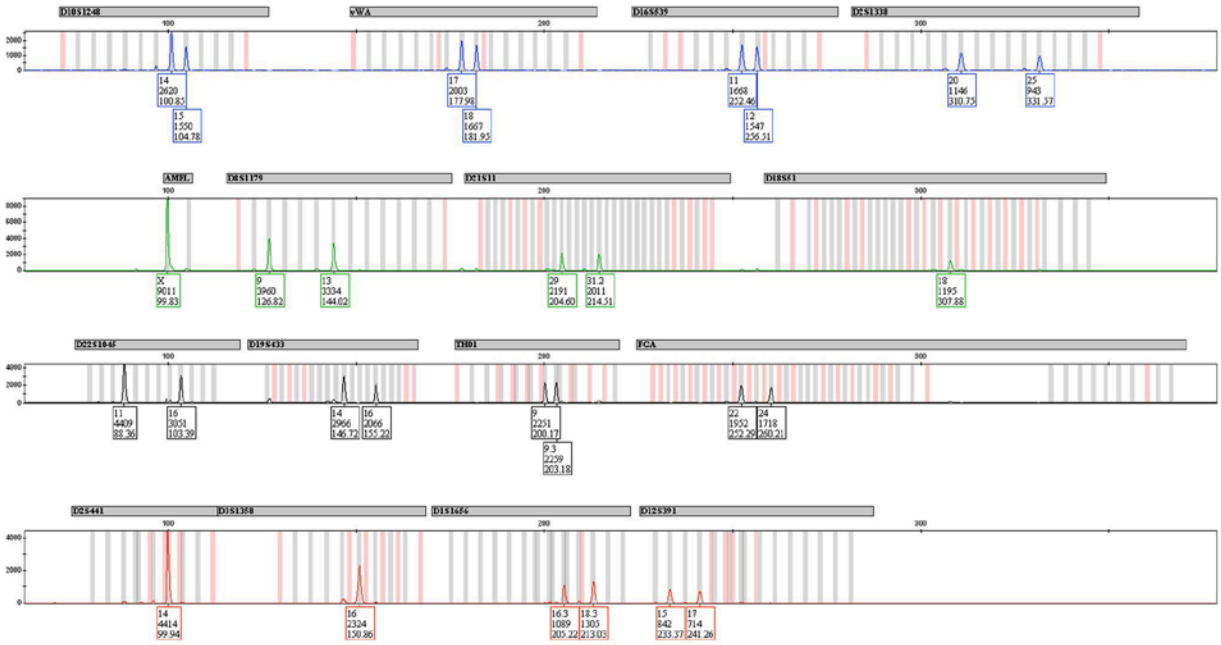

Fig. 1 Chromatogram of nuclear DNA from a fingernail clipping exhibiting a full DNA profile

(eight profiles in total). A presumption in sampling DNA directly is that nuclear material is present on the surface of the sample and is released and amplified during PCR. Fingernails would come into contact with foreign DNA during daily activity, and it would not be unexpected to see this additional DNA when sampling directly or via extraction methods [13].

A DNA profile containing five or more complete STR loci was obtained from 95 % of the samples tested using direct PCR. The profiles obtained from extracted DNA displayed similar success rates; however this can vary greatly between different extraction methods. Matte et al. [12] used wooden scrapers to obtain DNA from fingernails and found that between 36 and 87 % of their control samples (washed nails) yielded sufficient DNA for amplification using a 9 STR loci kit, depending on the extraction method used, but make no comment on the quality of the profiles obtained.

The DNA profiles obtained from clean washed fingernails in this study generated mostly single source profiles, or displayed a clear major profile if additional minor alleles were present; making them ideal for fast human identification, such as mass disaster victim identification where time and resources are limited. The successful recovery of DNA from fingernails that have been subjected to harsh conditions that may replicate mass disaster scenarios, such as water submersion, has been reported previously [14], indicating the robust nature of fingernails and their ability to hold DNA. Fingernail clippings do not need any special storage (such as refrigeration) and due to the small amount of sample needed, additional testing can be carried out using direct and standard extraction methods if a repeat test is required.

Unwashed nail clippings could also be processed directly for the purpose of obtaining foreign DNA as a victim may have come in close contact with a

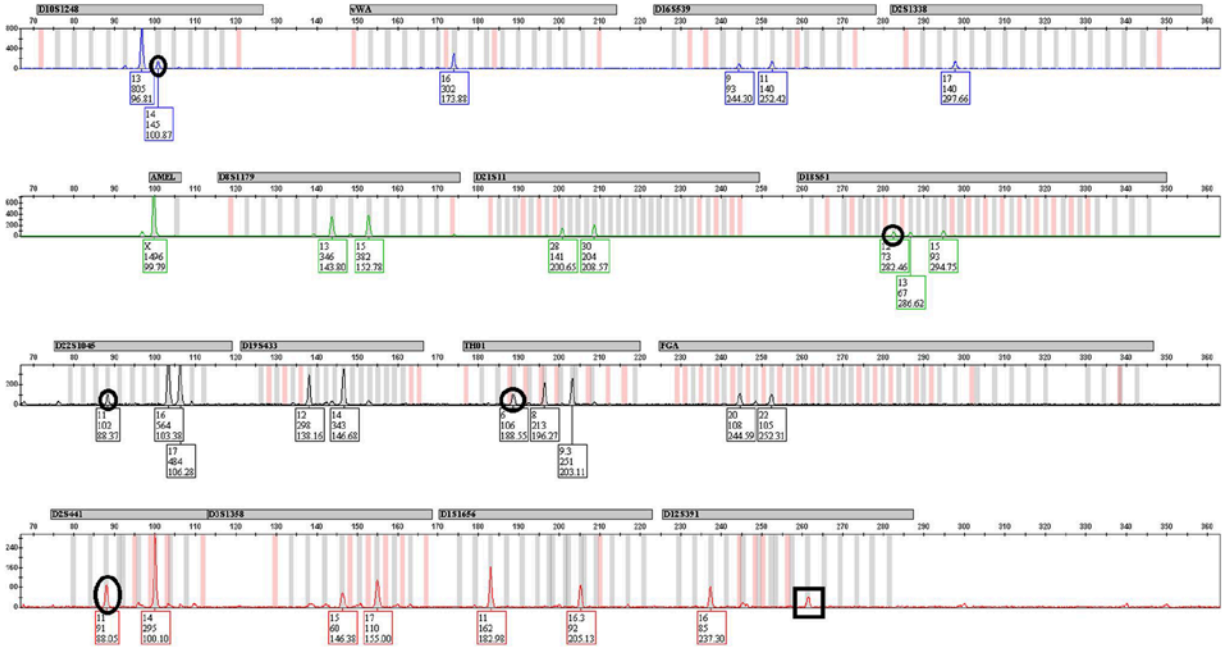

Fig. 2 Chromatogram of nuclear DNA from a fingernail clipping exhibiting a mixed DNA profile. Minor allelic contributions can be observed at the *circled* loci. Drop-out of the major component observed at locus D12S391 in the *square*

perpetrator. Foreign DNA recovered from fingernails can be significant evidence in a forensic investigation [15–17]. Direct PCR maximized the amount of DNA available for PCR as it is not being lost to the extraction process [5, 8, 18].

Conclusion

Direct PCR produced DNA profiles from a small fingernail clipping that could be uploaded to the NCIDD in 95 % of samples tested. This is a substantial increase compared to the process of performing standard DNA extraction then amplification of the extract [12] and greatly reduces the time and money spent processing samples. The profiles obtained were of higher quality than the extracted samples in this study, showing a higher heterozygous peak balance and limited effects from overloading. It was found that direct PCR of some fingernail clippings produced over-loaded DNA profiles after standard 29 amplification cycles and we recommend a dilution of the product prior to electrophoresis of the sample.

Only two samples failed to produce up-loadable profiles. One of these samples produced no alleles, whereas the other produced seven alleles (including amelogenin) across four loci. As each sample only required a 4 mm^2 section of a single fingernail clipping, additional testing either by direct PCR or standard extraction methods can be carried out if required. This simple process of direct PCR from fingernail clippings can be readily adopted for use into forensic DNA practice as standard validated methods were used and we demonstrate that the process has the capability of generating high quality full DNA profiles in reduced time.

Key points

1. We report on a successful and novel method for obtaining DNA profiles from fingernail clippings using direct PCR.
2. Profiles that were up-loadable to the Australian National DNA Database were obtained from 95 % of the samples tested.
3. The standard protocol for DNA amplification from the NGM™ STR typing kit was not modified, allowing for fast implementation into forensic laboratories.
4. Only 4 mm^2 of fingernail sample is required for testing, allowing for retesting or standard extraction testing if required. Standard extraction generally involves the "pooling" of all fingernail clippings taken.
5. Direct PCR provides more DNA to PCR than standard extraction methods, resulting in more useful DNA profiles therefore saving time and money in forensic casework.

6. Fingernail clippings could be used for fast human identification in disaster situations.

5.3 Applications

The challenges faced with mass disaster investigations (DVI) and the subsequent victim identification has been well documented [10, 11, 13-17]. An extensive amount of evidence and scene management is required immediately after a mass disaster and can be hindered by the type of disaster, the terrain, the overall environmental conditions, the number of staff and organisations available for assistance, and the coordination of those teams, just to name a few. DNA evidence must also be documented, collected and stored appropriately and as fast as possible to reduce further contamination and degradation. Often due to the sheer size of a mass disaster operation, DNA degradation is very difficult to avoid thus creating delays in identification, and increasing the costs of the downstream processes. DNA analysis has often required the use of shorter primer sets, or mini-STRs, to help combat the DNA breakdown and degradation often associated with DVI cases [18-22]. The nature of the DVI can mean DNA degradation is unavoidable, as in the case of bombing or plane crashes. Some studies have even focused on the use of SNPs or mitochondrial DNA to overcome these same issues [23-27].

As mentioned in *sections 5.1* and *5.2*, the human fingernail has the propensity to hold DNA within its keratin structure for long periods of time, even through extreme environmental conditions. This sample type therefore has great benefits for DVI situations, particularly when it comes to storage of the sample. Fingernails do not require refrigeration, and can be collected and stored very quickly leading for the next stages of processing. Refrigeration of samples is a huge hurdle when it comes to mass numbers of victims, especially in remote or humid locations. When sampling fingernails, only a small section is required for direct PCR, allowing for resampling or further testing if required. Fingernails and human hair, where available, would be an effective additional (or alternative) source for DNA sampling in DVI cases to traditional blood or tissue. Both sample types have shown to work well with standard STR typing, without the need to use modified or additional methods for processing [28-30]. The speed of processing of these sample types also decreases the overall cost of processing – both are huge benefits in DVI when pressure surrounds every aspect of mass disaster investigations.

5.4 Concluding Remarks

Based on the results of this study, the use of direct PCR with human fingernails has improved the probability of obtaining meaningful profiles compared to processing the same samples using standard extraction methods, as well as reducing the time and costs involved with the analysis process. Without the need to modify or adjust validated methods, direct PCR of human fingernails can be applied in investigations quickly. The robustness of fingernails and their propensity to hold DNA through extreme environmental conditions is greatly beneficial to DVI and missing person investigations that are time sensitive. The data continues to support the theory that nuclear and cell-free DNA are present on the surface of the substrate, and is easily made available to the PCR matrix during the direct amplification process.

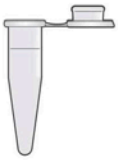
Nail Study

- 40 fingernail clippings from 8 donors
  - Collected post hand-washing/ shower
- ~2 mm² of fingernail used
- Placed directly into PCR tube
- NGM™ human identification kit used
  - 15 STR loci + amelogenin
- Standard 29 cycles (NO increase or adjustment!)
  - Typically increased for low copy DNA

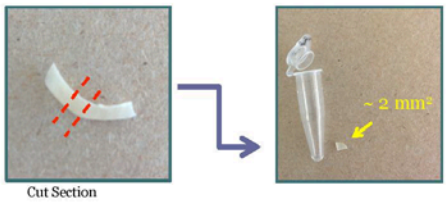
Typical Process

- No Standard method
- Clippings from one or both hands pooled for single extraction
- Scrapings under nails pooled
- Swabbing nails

One extraction



Fingernail Clipping



Cut Section

Theory: Nuclear DNA present on underside of fingernail
- Nucleated cells or cell free DNA

Source: Skin secretion or sebum

DNA - single source or mixed?

- Previous study (Extraction method)[1]
  - Foreign DNA contribution between 13 – 23 %
  - Mostly linked to cohabiting partner
- Presence of foreign DNA not unexpected
  - Daily activities

Profiles up-loadable to the National DNA database (Australia)				Total observed foreign DNA	
95%				22.5%	

Results

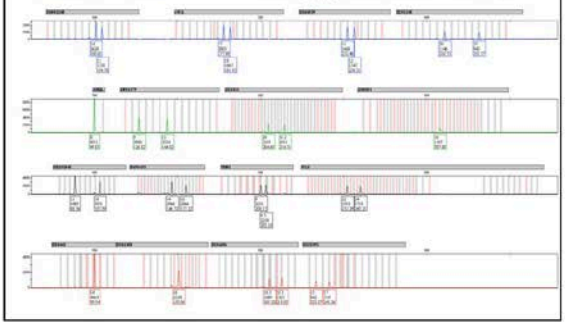
DNA obtained: 38 Samples
29 Single Source
9 Mixed Source*

* mixed profiles had clear Major and Minor Components

All minor alleles attributed to cohabiter of donor

Full Profile

average peak balance = 79.9 %



Additional Alleles + Drop out

Optimisation

- STR kits are optimised for 1 ng input of DNA
- Input DNA unknown for Direct PCR samples
- Too much DNA can lead to:
  - Peak Imbalance
  - Noisy Baseline
  - Pull-up
  - Split peaks

Diluting PCR products
can reduce these affects

Before Dilution / After Dilution

Application

- Fast Human Identification
  - Clean nails mostly single sourced/ clear major
  - Nails can be washed pre or post collection
  - Special storage not required
  - DVI identification
  - Robust material
    - Study shows DNA can withstand harsh conditions on fingernails and can still be retrieved [2]

[2] Harbison SA, Petricevic SF, Vintiner SK. The persistence of DNA under fingernails following submersion in water. In: Brinkman B, Carracedo A, editors. Progress in Forensic Genetics 9. Int Congress Ser. Amsterdam: Elsevier Science Bv; 2003. p. 809-13.

Application

- Casework
  - Focuses on mixed profiles (assaults, close contact)
  - Direct PCR yields higher DNA

Summary

- Extraction process circumvented
  - DNA not lost via wash steps or tube changes
  - Greater DNA yield
- Cost effective and time saving
- Small sample required
  - Allows for retesting via Direct or Extraction
- Minimal to no changes made to **protocols** of already validated STR human identification kits
  - Easy & quick implementation in forensic labs

Successful direct amplification of nuclear markers from fingernail clippings

Renée Ottens[1], Adrian Linacre[2]

1 School of Biological Science, Flinders University, Bedford Park, SA, Australia, renee.ottens@flinders.edu.au

2 School of Biological Science, Flinders University, Bedford Park, SA, Australia, adrian.linacre@flinders.edu.au

We report on successful direct amplification of DNA profiles from fingernail clippings. The collection of fingernail clippings for DNA analysis is fast and non-invasive. Fingernails will not degrade in the same manner as other biological materials and do not need special storage. This makes fingernails an ideal sample type in mass disaster circumstances where storage and conditions may not be optimal. Direct amplification has the advantages of increasing PCR sensitivity and DNA yield, allowing for human identification to be made in a significantly reduced time. Using the NGM™ 15 loci STR kit, a small section (~ 2 mm^2) of clipped nail was placed directly into a 0.2 mL thin walled tube for amplification. No adjustments to the manufacturer's protocol were made except the addition of 5 units of AmpliTaq Gold® DNA polymerase. Ten nail clippings (one from each finger) were analysed from seven individuals. Full profiles were obtained routinely after 29 cycles with no inherent stochastic effects thus reducing time, cost and increasing the opportunity to obtain an STR profile.

CHAPTER 6

Direct PCR from Fibres

Blackie, R., D. Taylor, and A. Linacre, *DNA profiles from clothing fibers using direct PCR.* Forensic Science, Medicine, and Pathology, 2016. **12**(3): p. 331-335.

Direct PCR from Fibres

6.1 Preface

Similarly to human and animal hairs, single fibres or items of clothing may often be present at crime scenes, potentially offering valuable forensic information. Single fibres may come loose from their original source and be transferred to other surfaces or areas during direct or indirect physical contact, such as a struggle during a physical assault or in the attempt to remove evidence of a crime [1]. Single fibres are typically analysed microscopically to identify morphological features such as weave pattern, colour, or whether the fibre is natural, man-made or both [2, 3]. The morphology of a fibre can provide information to assist in linking it to its original source or location. The addition of autosomal DNA information from a single fibre could provide new avenues for investigation, with the ability to link a person, as well as a garment, to a crime. This chapter explores the use of direct PCR with fibres from clothing, to offer an additional analysis tool in criminal investigations. The following sections explore the testing of fibres, using direct PCR, within the Flinders University DNA laboratory (*6.2*), the application of single fibres as a substrate for direct PCR (*6.3*), as well as the application of single fibres in casework and future implementation of the technique (*6.4*).

6.2 Preliminary data

To investigate the suitability of single fibres as a substrate for direct PCR methods, several preliminary experiments were conducted. Firstly, to ascertain if inhibition or over-amplification would occur, the following conditions were set up: using sterilised white cotton, fabric squares measuring approximately 2 mm x 2 mm were held for 15 seconds (Figure 6.1); single fibres measuring approximately 5 mm were held for 15 seconds; 10 µL of saliva was pipetted onto fabric squares and left to dry; and 1 ng of control DNA (extracted from individual's buccal swab) was pipetted onto fabric squares and left to dry. All fabric squares and single fibres came from the same source of white cotton, which had been sterilised under ultra violet light for 10 minutes. Hands were washed with soap and water 30 minutes prior to holding fabric squares and single fibres. Ten of each sample type was processed.

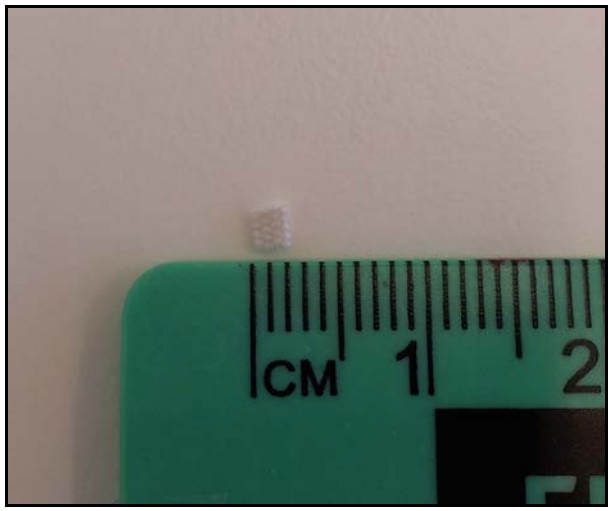

Figure 6.1 – Example of size of white cotton fabric cut for direct PCR used in control and preliminary experiments.

All samples were amplified using the NGM™ kit (Life Technologies, Victoria, Australia). Each sample (i.e. either the entire material square, or the entire fibre) was prepared in a 0.2 mL thin walled tube containing 25 µL of reagents following the manufacturer's instructions. A total of 29 PCR cycles was performed on a GeneAmp® 9700 96-well thermal cycler (Life Technologies) following manufacturer's instructions. PCR products (1 µL) were combined with 0.5 µL Liz 500™ (Life Technologies) separated using a 3130*xl* Genetic Analyser (Life Technologies). The data were analysed using GeneMapper® ID v3.2 (Life Technologies) with a threshold of 50 RFU for allele assignment.

Touched fabric square samples all produced profiles of six alleles or less (counting homozygous loci as a single allele to represent an unknown reference profile). However, 50 % of these samples showed a greater number of alleles between 40 – 49 RFU (represented by dots in Table 6.1), just below the 50 RFU threshold, indicating the possibility for protocol enhancement (such as cycle number increase) or analysis using a continuous software programme such as STRmix™ or TrueAllele® where peaks at lower analytical thresholds can be considered by modelling signal and noise [4-7]. Utilising the information down to 40 RFU would mean three of the ten touched fabric square samples would be considered partial profiles (five or more complete STR loci), and therefore up-loadable to the Australian NCIDD.

Nine of ten single fibre samples produced profiles of five or more complete STR loci, with seven of these profiles containing between 1-3 non-donor alleles (Table 6.2). Although the fabric squares have a higher surface area than the single fibres during contact, the single fibres performed better. It is possible that the larger physical space of the fabric squares within the PCR tube, and therefore PCR matrix, somehow prevents all available surface DNA from being released. DNA retention to the fabric squares is explored later in this section. As a single fibre is used in the analysis it is assumed that any resulting DNA profile will be mostly attributed to the individual touching the fibre. The individual touched the fibres and fabrics 30 minutes after washing their hands. During the 30-minute interval, the individual commenced regular activities. With this in mind, secondary transfer of DNA needs to be considered when analysing profiles obtained [1, 8-10]. It cannot be assumed that a DNA profile from a single fibre is wholly from the individual touching the item.

All fabric square samples with saliva returned full profiles of the individual (Table 6.3). DNA was not extracted from the saliva prior to placing on the fabric; it is assumed that cell-free DNA would be present in the saliva [11, 12], and that cell membranes would also be broken down during the initial heating stage of the PCR process releasing DNA into the PCR matrix.

Table 6.1 – NGM™ profiles showing allele call, RFU value and profile percentage obtained from ten fabric square (white cotton) samples that were held for 15 seconds and amplified using direct PCR methods at 29 cycles. Dots indicate alleles present but less than 50 RFU threshold.

As mentioned previously in *section 2.5*, the level of fluorescence in a treated DNA sample can be used to indicate how much DNA is present [13, 14]. The data from *section 2.5* supported a linear correlation between DNA mass and the RFU value, therefore a decrease in RFU value would be indicative of a loss of DNA mass. This same principle is applied to determine if DNA is retained on fabric or released entirely during direct PCR. The average RFU values of positive control samples of known DNA masses (2800M, Promega, Victoria, Australia) at 0, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9 and 1 ng were compared to the average RFU values of the same DNA concentrations amplified directly from fabric squares. Fabric samples were prepared by pipetting the series of control DNA (2800M) onto sterilised fabric squares measuring 2 mm x 2 mm and allowed to dry. This was prepared three times for each mass of DNA (0 – 1 ng) for a total of 33 fabric samples. Each sample was placed directly into a 0.2 mL thin walled tube containing 25 µL of reagents from the NGM^{TM} kit, following the manufacturer's instructions. A total of 29 PCR cycles was performed on a GeneAmp® 9700 96-well thermal cycler following manufacturer's instructions. PCR products (1 µL) were combined with 0.5 µL Liz 500™ separated using a 3130*xl* Genetic Analyser. The data were analysed using GeneMapper® ID v3.2 with a threshold of 50 RFU for allele assignment. A single set of the positive control samples were amplified in the same way. All samples were run in triplicate on the 3130*xl* for a total data set of 33 positive control profiles and 99 fabric profiles (see supplementary material: *raw data examples*). The linear correlation between DNA mass and RFU value was confirmed for both sets of data, with R^2 values above 0.9. The data indicated that overall there was an average RFU value decrease of 21.7 % between the control and fabric samples, suggesting that approximately one fifth of DNA present on this fabric type is not released into the PCR matrix during amplification.

There is obviously a wide range of variables that could contribute to the availability of DNA on the fabric and how much is released to the PCR matrix. This could include the composition of the fabric: if it is synthetic, natural or a combination of both; any dyes present that may inhibit the direct PCR process; exposure of the DNA to environmental pressures; the type of DNA left behind; how much pressure is applied to the fabric through touch; an individual's 'shedder' status; as well as transference factors (direct, or indirect) to name a few. It would be unrealistic to explore all of these factors, and many are constantly changing due to a range of other variable conditions. With these issues in mind, *section 6.3* explores the potential of using single fibres from worn clothing items with direct PCR. The clothing items were selected randomly and consist of various fabric types and colours, as best to mimic a casework scenario.

TECHNICAL REPORT

DNA profiles from clothing fibers using direct PCR

Renée Blackie[1] · **Duncan Taylor**[1,2] · **Adrian Linacre**[1]

Accepted: 20 May 2016 / Published online: 16 July 2016

Abstract We report on the successful use of direct PCR amplification of single fibers from items of worn clothing. Items of clothing were worn throughout the course of a day, with the individual commencing regular activities. Single fibers were taken from the cuff of the clothing at regular intervals and amplified directly. The same areas were subjected to tape-lifting, and also amplified directly for comparison. The NGM™ kit that amplifies 15 STR loci plus amelogenin was used. A total of 35 single fiber samples were processed and analyzed from five items of clothing, with 81 % of samples returning a profile of 14 alleles or more. All tape-lift samples amplified directly produced DNA profiles of 15 alleles or more. The aim was to develop a simple, operational method that could be used routinely in forensic science casework and that has the potential to generate more complete profiles, which would not be detected using standard extraction methods on this type of sample. For ease of implementation, the process also adheres to standard methods with no increase in the cycle number.

Introduction

Direct PCR was first used on forensic relevant samples in 2010, illustrating the potential benefit of using this technique with fibers [1]. Fibers have not been explored in any further detail using this technique since then, with much of the research focusing on other sample types such as hair, fingernails, blood, and trace DNA on various substrates [2–11]. The presence of PCR inhibitors in fabrics, such as dyes, can represent a challenge when directly amplifying single fibers. The previous two decades have seen a vast improvement in all aspects of the DNA profiling process, providing highly robust human identification kits that are more capable of dealing with PCR inhibition than ever before [12, 13]. Even with the increase in sensitivity of modern STR typing kits, trace amounts of nuclear DNA still limits the possibility of generating meaningful DNA profiles using current standard operating procedures. Direct PCR therefore has the potential to increase the number of alleles generated from trace DNA samples. By circumventing the extraction process, time and costs are also reduced, as well as reducing laboratory error or exogenous DNA contamination.

Clothing found at crime scenes can be analyzed for DNA using a variety of techniques such as swabbing, tape-lifting, or extracting directly from cut sections of the fabric [1]. Single fibers, however, are less likely to be processed for DNA and instead are analyzed microscopically [14–16]. The ability to obtain nuclear DNA profiles from single fibers would be of great benefit to investigations, especially where microscopy may fail to provide substantial information. We report on the successful direct amplification of single fibers from worn items using the NGM™ human identification kit.

Materials and methods

Samples

A female participant wore five different long-sleeved clothing items of varying fabric compositions and colors, for 12 h each. The five items were: A1—a maroon cardigan, cotton; A2—a cream with light gray print sweater, cotton; A3—a light gray with dark gray print sweater, cotton; A4—a dark green cardigan, cotton/acrylic; and A5—a light gray cardigan, 80 % acrylic/20 % nylon. The individual washed each item prior to wearing, and was the only individual in direct contact with them between washing and wearing the items. The items were not removed from the individual during the time period. A single fiber, approximately 5 mm in length, was cut from the inside seam of the right cuff of each item at hours 0, 2, 4, 6.5, 9, and 11 of wear, with a tape-lift conducted after 12 h of wear. Samples collected at time points 0, 2, 4, 6.5, and 9 h were amplified using direct PCR methods, with the 11-h fiber samples undergoing standard extraction methods. All clothing items were worn during the course of a regular workday where normal office-based activity was conducted for that individual.

Tape-lifts were conducted on each worn item on the inside of the right cuff using Sellotape® brand adhesive tape. Tape measuring approximately 5 cm × 2.5 cm in size was used for each tape-lift. The tape was pressed over and removed from the targeted area 20 times. A 1 cm × 1 cm section was removed from the center of the tape and placed into a 0.2 mL thin walled tube for direct PCR amplification.

A total of 35 samples were processed and analyzed from the five items of clothing. DNA extracts from buccal swabs were also provided as references of the participant and their cohabiting partner. The fibers were not treated in any manner prior to amplification.

Direct PCR amplification and conditions

Direct PCR was conducted by placing the relevant sample, either a single fiber or section of adhesive tape, into a 0.2 mL thin walled tube containing 10 μL of PCR master mix from the AmpFℓSTR® NGM™ kit (Life Technologies, Victoria, Australia) along with 5 μL of the primer mix and 1 μL (5 U) of additional AmpliTaq Gold® DNA polymerase (Life Technologies). The addition of the AmpliTaq Gold® DNA polymerase is to increase the overall units of enzyme in the reaction to assist in overcoming inhibitors that may be present on the fiber. A further 9 μL of sterile H_2O were added to make the final volume 25 μL. The amplification was conducted in a GeneAmp® System 9600 thermal cycler (Life Technologies) using the manufacturer's recommended conditions. During PCR, 29 cycles was used for all reactions. The NGM™ kit amplifies 15 STR loci plus the amelogenin locus.

DNA extraction from single fibers

A single fiber from each item, measuring approximately 5 mm, was extracted using aQIAamp® DNA Mini Kit. A total of five extractions were performed following the manufacturer's protocol for DNA purification from buccal swabs (as swabs are made from fibers). The fibers were incubated for 1 h and eluted in a final volume of 30 μL. The DNA was quantified using a Qubit® 2.0 Fluorometer (Life Technologies). From these extracts, 10 μL of DNA was used in the PCR setup using the same conditions as for the direct fiber samples.

Capillary electrophoresis

Capillary electrophoresis was performed on an ABI 3130*xl* Genetic Analyser (Life Technologies) using POP-4™ polymer (Applied Biosystems). An aliquot of 1 μL of the PCR sample was added to a solution of 0.5 μL of ABI GeneScan-600 LIZ® Size Standard and 9.5 μL of Hi-Di™ Formamide. Samples were then denatured at 95 °C for 3 min. Electrophoresis was conducted at 3 kV with a 10 s injection. The data were analyzed using GeneMapper® v3.2. The detection threshold was set at 50 relative fluorescence units (RFU).

Results

Two of the five samples tested at time 0 h, directly after washing, produced just one allele each—the X-chromosome amelogenin marker. All samples from item A4 produced no alleles, and upon further testing it was concluded that an inhibitor, most likely the dye (a dark green), had interfered with the direct PCR process. No alleles were observed for the five 11-h fiber samples that were processed using standard extraction methods. The remaining 16 timed fiber samples (2, 4, 6.5, and 9-h wear) amplified directly using the NGM™ kit were analyzed (see Table 1).

All fiber samples, except for two, produced mixed DNA profiles displaying major and minor contributors. A single minor allele was observed in seven of these samples, with the remaining samples containing between two and 15 minor alleles. All alleles obtained could be attributed to the donor or their cohabiting partner. Only one profile contained a single allele that could not be attributed to either. Item A3 at two time points (4 and 9 h) produced profiles

Table 1 Summary of alleles obtained from single fibers amplified directly from items worn over a 9-h period

Item Hours item worn for	A1 Total number of alleles obtained	A2	A3	A4	A5
0	1	0	0	0	1
2	15 (0)	29 (1)	3 (1)	0	30 (6)
4	16 (1)	21 (0)	14 (14)	0	33 (7)
6.5	25 (9)	5 (1)	2 (1)	0	24 (1)
9	42 (15)	17 (2)	21 (21)	0	14 (1)
11[a]	0	0	0	0	0
12[b]	39 (15)	43 (16)	15 (6)	0	22 (8)

Data includes 11-h time point of fibers processed with standard extraction methods, and 12-h time point of tape-lifts amplified directly. Number of foreign/non-donor alleles in brackets

[a] 11-h time point samples are single fibers processed with standard extraction methods

[b] 12-h time point samples are from directly amplifying a section of adhesive tape after a tape-lift

comprising of alleles *only* from the cohabiting partner, and none from the participant wearing the item. Time points 2 and 6.5 h produced insignificant data of three alleles or less. There is no distinguishable pattern of allelic increase when items are worn for longer periods of time (Table 1).

A full DNA profile of the participant, comprising all 15 STR loci and the amelogenin locus, was obtained from two samples (example Fig. 1). A further nine samples produced a DNA profile of five or more complete STR loci (partial profile) that could be uploaded to the Australian National Criminal DNA Database (NCIDD). Three samples in total produced five alleles or less, with two samples producing 14 and 21 alleles of the cohabiter only. An additional four profiles, ranging between 15 and 43 alleles, were obtained using direct amplification of the adhesive tape, with profiles typically showing a large number of non-donor alleles (example Fig. 2).

Discussion

A presumption in sampling DNA directly is that nuclear material is present on the surface of the sample and is released and amplified during PCR. The human body is constantly shedding dead skin, perspiring, and coming into contact with foreign DNA during daily activity. To see non-donor DNA appearing on the fibers of worn items, via secondary and/or subsequent DNA transfer, would not be unexpected when sampling directly [17–19]. The participant of this study was asked if there was any change to their routine on the day they wore item A3, as it produced two profiles comprising of alleles only from their cohabiting partner. They noted the only significant difference was that they did not shower in the morning before work, but at night instead. As the participant and their partner

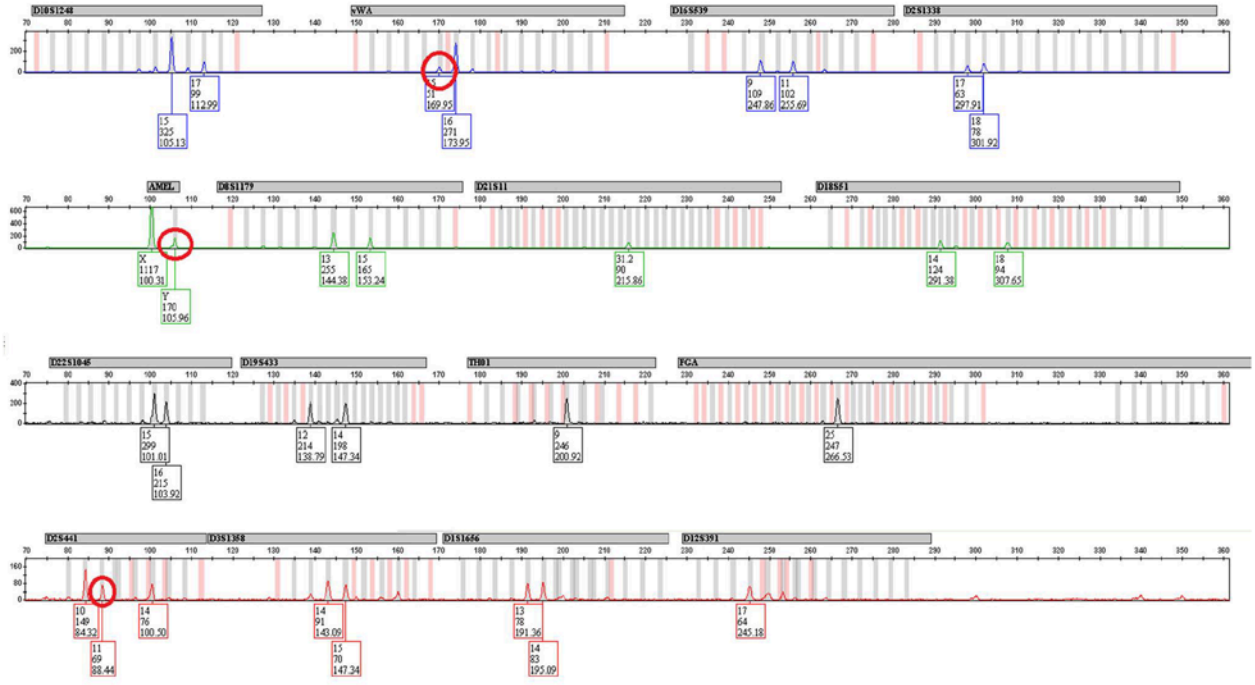

Fig. 1 Chromatogram of nuclear DNA from a single clothing fiber after 2 h of wear. A fiber was amplified directly using AmpF*ℓ*STR® NGM™ kit at 29 cycles on a GeneAmp® System 9600 thermal cycler. Sample was injected on an Applied Biosystems 3130*xl* Genetic Analyser at 3 kV for 10 s. Non-donor allelic contributions are highlighted with *circles*

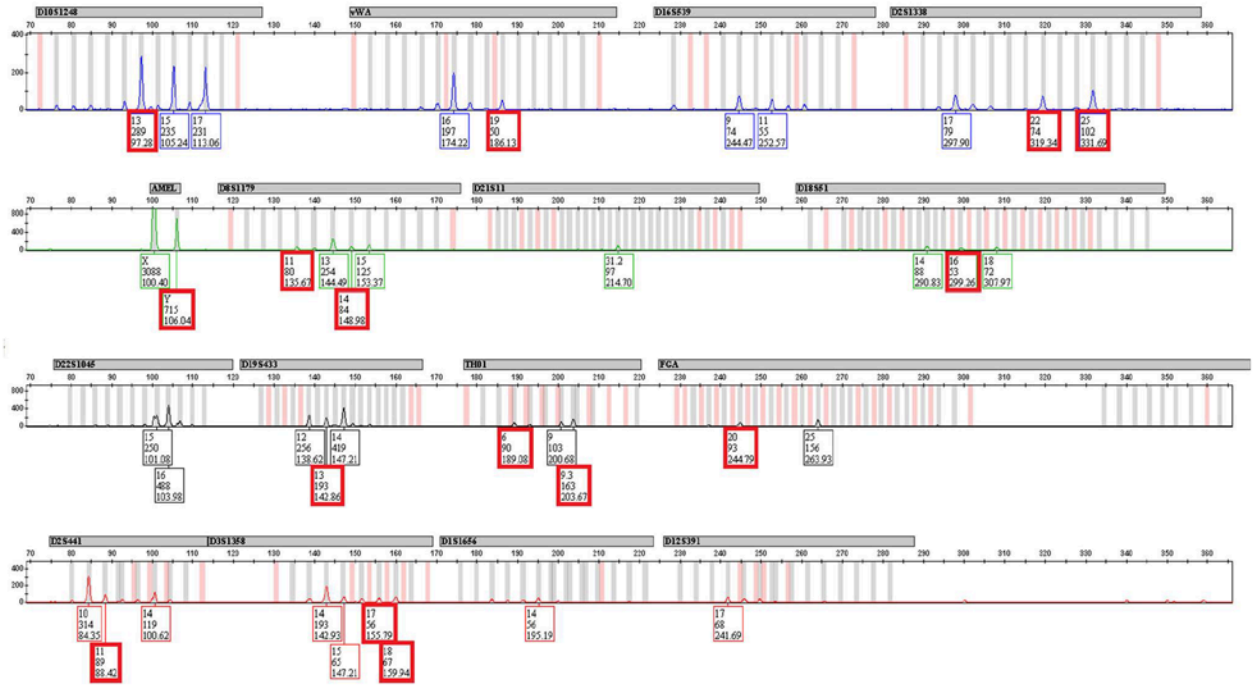

Fig. 2 Chromatogram of nuclear DNA from a tape-lift of clothing item after 12 h of wear. A 1 cm^2 section of tape was amplified directly using AmpF*ℓ*STR® NGM™ kit at 29 cycles on a GeneAmp® System 9600 thermal cycler. Sample was injected on an Applied Biosystems 3130*xl* Genetic Analyser at 3 kV for 10 s. Non-donor allelic contributions are highlighted with *boxes*

share a bed, we propose that there was opportunity for the participant to accumulate shed cells and free DNA from their partner onto their own body during the night. Thus allowing any foreign DNA collected on the skin, in this case that of their partner, to be readily transferable to worn items of clothing.

The presence of DNA on clothing directly after washing has also been previously reported [20]; indicating DNA can be transferred between items during the wash cycle. This could possibly explain alleles present at the 0 h time point. However, improved multiplexes and instrumentation also greatly increases the sensitivity of detection, allowing DNA profiles to be obtained from just a few cells, or cell-free DNA [21–24]. By amplifying the samples directly, the amount of DNA available to the PCR matrix is maximized, as the nuclear DNA is not lost to the extraction process [1, 4, 5]. Therefore, any DNA or cell-free DNA that is not destroyed during the washing process, and any contact made with foreign DNA, has a higher chance of being detected during direct amplification.

The profiles obtained from direct PCR of tape-lifts are consistent with previous studies, showing a higher number of alleles obtained using tape-lift extraction compared to other extraction methods such as swabbing [25–27]. These results are also consistent with previous research indicating that DNA from the non-wearer is often found on items of clothing, mostly detected as a minor profile [18, 28, 29]. The direct PCR technique combined with the tape-lift extraction is a much faster process than previously described, and does not require substantial adaption to current amplification methods.

Conclusion

Direct PCR of single fibers produced DNA profiles of at least 14 alleles or more, which could be uploaded to the Australian NCIDD in 81 % of samples tested. Similarly, all tape-lift samples amplified directly produced DNA profiles of 15 alleles or more. Only three single fiber samples failed to produce up-loadable profiles. The results are a significant increase compared to the process of performing standard DNA extraction prior to amplification, where single fibers failed to produce any alleles. Only one item tested contained direct PCR inhibitors within the fiber—most likely the composition of dyes.

Each sample only required a single fiber, or a small cut-out of adhesive tape, allowing for additional testing to occur, as well as targeting several areas of the clothing item if required. This simple process of direct PCR from single fibers and adhesive tape can be readily adopted for use into forensic DNA practice as standard validated methods were used. DNA profiles can be generated at a reduced cost and

faster than when standard extraction methods are implemented, producing higher quality results.

Key points

1. We describe a successful method for obtaining DNA profiles from single clothing fibers and adhesive tape using direct PCR.
2. Profiles that were suitable for up-loading to the Australian National Criminal DNA Database were obtained from 81 % of the single fiber samples tested.
3. The standard protocol for DNA amplification from the NGM™ STR typing kit was not modified, allowing for fast implementation into forensic laboratories.
4. Only a single fiber is required for testing, allowing for testing of multiple sections of clothing.
5. Direct PCR provides more DNA to the PCR matrix than standard extraction methods, resulting in more useful DNA profiles, therefore saving time and money in forensic casework.

Acknowledgments Funding was provided by the Attorney General's Department of South Australia.

6.4 Applications

Section 6.3 highlights the potential of using single fibres from clothing in conjunction with direct PCR. Amplifying sections of tape-lifts directly also provided a higher number of alleles than standard extraction methods. Using multiple tape-lifts and single fibres from one item of clothing could possibly provide a series of DNA profiles to assist in an investigation where DNA information may not be generated otherwise. Consensus and composite profiling can also be implemented using data generated from the direct amplification of these samples. Composite profiling combines all alleles observed from multiple replicates. An allele only needs to appear once to be recorded. Consensus profiling requires alleles to appear more than once and is only recorded if observed in each replicate (Figure 6.2).

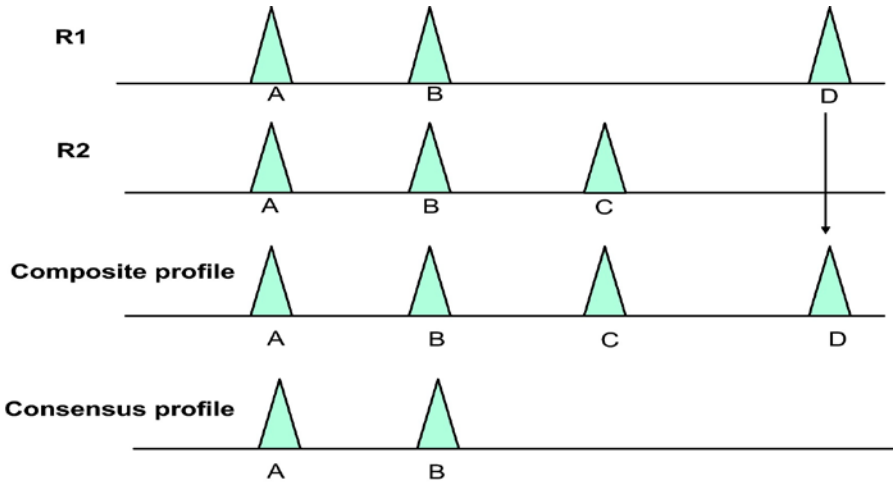

Figure 6.2 – Understanding the difference between composite and consensus profiles by comparing two replicates, R1 and R2. The consensus profile only contains alleles A and B as they appear in both replicates, whereas the composite profile contains all alleles (A, B, C and D) observed in both replicates. *Figure source: Bright [15]*.

Caution should be observed when applying these two analysis techniques. Consensus and composite profiles are created by amplifying DNA from a single extraction multiple times, or by injecting the same PCR product multiple times. Only the latter should be applied when using direct PCR methods, as per the recommendations of the SWGDAM guideline for interpreting composite and consensus profiles [16]. It should be noted that only American laboratories are required to follow SWGDAM guidelines. Further research using direct PCR and consensus profiling may need to be conducted to determine how conservative the profiles are, that alleles are associated as donor or non-donor (major or minor contributors) with a reduction or elimination of allelic drop-in [17, 18]. Semi-continuous or fully continuous methods that utilise all the information from replicates

generated from a single DNA extract [19], could also be applied to profiles run from the same direct PCR product.

Projecting forward into the use of fibres and direct PCR would be to investigate the suitability of other common fabric types with this method. The items used in the preliminary experiments (*section 6.2*) and explored further in *section 6.3* were either cotton or mostly cotton blends. Denim would be an obvious choice, however it is likely that indigo dyes commonly present in denim will inhibit the PCR process [20, 21]. As mentioned previously, it would be unrealistic to explore the suitability of all fibre types, however many common blends are yet to be investigated. Textile fibres from carpet, tents, sails, ropes and cordages are also commonly found at crime scenes [2] and are worthy of investigation using direct amplification methods.

It is also clear that directly amplifying sections of a tape-lift yields impressive data that would not be obtained by standard methods, or without an increase in cycle number. Tape-lifting is the most effective and common method to remove trace evidence from items, clothing, and corpses at a crime scene [2]. This has long been the standard procedure for fibre investigations [2, 22]. Tape-lifts are able to collect foreign hairs and fibres, as well as skin flakes, and any other DNA (cell-free) that has been transferred directly or indirectly. The identification of skin flakes on tape-lifts using microscopy has enabled the DNA to be successfully extracted and amplified [22]. The process however, is laborious and only resulted in DNA profiles from approximately 15 % of 500 individually extracted skin flakes. From the successful samples, only 5 % yielded full DNA profiles. LT-DNA typing methods using 33 cycles were implemented to obtain this data. Using standard methods, only 0.5 – 1 % of selected samples yielded full profiles. Although these success rates can be considered low, it has opened up a pathway to re-examine tape-lifts for cellular DNA where previously only fibres and hairs were collected for examination. This method was applied to cold cases and resulted in a conviction in two cases [22]. Direct amplification of tape-lifts from cold cases has the potential to improve on these results as cycle number increase is not required, and significant DNA mass is not lost to the extraction step. The process is significantly faster, and multiple samples can be amplified from a single tape-lift.

6.5 Concluding Remarks

Although this research conducted on fibres is considerably small in the vast world of fabrics, the benefits highlighted are huge. Two additional methods for acquiring DNA from fabrics include amplifying single fibres or small fragments directly, and using small sections of tape from a tape lift. Using these tools to complement current analysis techniques of fibres can offer investigators more information in a short amount of time. It is clear that there are limitations involved when using fibres as a direct PCR substrate, there are too many variables to investigate thoroughly, and inhibition from dyes will likely be an ongoing issue. The discrimination power offered by DNA however, is a valuable asset to any investigation and always worthy of pursuing. Like previous substrates, these methods do not require the enhancement of cycle number or significant protocol adjustments to those used in forensic laboratories on typical trace DNA samples.

Table 6a.6 – NGM™ profiles showing allele call and RFU value for triplicate samples of 0.6 ng of neat DNA (blue), and on white cotton fabric squares (green, yellow and red), amplified using direct PCR methods at 29 cycles. Results used to determine loss of DNA (or DNA retention to the fabric) based on RFU values.

Table 6a.8 – NGM™ profiles showing allele call and RFU value for triplicate samples of 0.8 ng of neat DNA (blue), and on white cotton fabric squares (green, yellow and red), amplified using direct PCR methods at 29 cycles. Results used to determine loss of DNA (or DNA retention to the fabric) based on RFU values.

CHAPTER 7

Direct Phenotypic SNPs

Manuscript prepared as: a technical note, Journal of Forensic Sciences.

Successful direct amplification of human hair and fingernails using IrisPlex SNP markers

Direct Phenotypic SNPs

7.1 Preface

SNP data have been used for over a decade to infer ancestry, lineage and human migration movement, in conjunction with Y-STR and mitochondrial DNA haplotypes [1-4]. However, using SNP data to predict phenotypes is a recent progression within the forensic science community [5-9]. As SNP amplicons are typically smaller than STR amplicons, there is a greater chance of obtaining valuable DNA information from difficult trace and degraded samples [10-13]. Although SNP data does not offer the same level of discrimination power for identification, standard STR profiles may not be of much significance if there is no reference profile or existing profile on a database for comparison. The use of phenotypic or ancestry SNPs, therefore, has the potential to aid in inclusion or exclusions of suspects or victims where no other information is available.

The first step of SNP analysis involves regular PCR techniques of small amplicons; therefore direct PCR can be applied at this stage in conjunction with samples that routinely amplify well with direct methods. The following sections investigate the application of single human hairs and fingernail clippings as substrates for direct PCR using IrisPlex SNP markers (*7.2*), and the future implementation and use of the direct PCR technique in conjunction with other SNP markers (*7.3*).

ABSTRACT

We report on the successful direct amplification of IrisPlex Single Nucleotide Polymorphism markers using single hair follicles and fingernail clippings. SNPs from the validated IrisPlex system were chosen. A section (~ 5 mm) of a single hair from the proximal tip, and a section of a fingernail clipping (~ 4 mm^2) were used separately in the initial PCR amplification. These were placed directly in the PCR tube. All following steps adhered to the IrisPlex protocol. Complete SNP profiles were obtained from all 25 single hair samples and 40 % of 25 nail samples with a further 28 % of nail samples yielding 4 out of the 6 targeted SNPs. In all cases the SNPs matched the reference profiles of the individuals tested. The results from this study highlight the potential use of DNA trace samples as a source for directly amplifying SNPs.

Keywords: forensic science, direct PCR, anagen hairs, fingernail fragments, IrisPlex, SNPs

The use of Single Nucleotide Polymorphisms (SNPs) in forensic science is becoming popular due to the ability to provide additional informative data to the use of standard Short Tandem Repeats (STRs) (1-10). The STR profile from a forensic sample is only of value if it can be matched to a reference profile or a DNA profile held on a national database. SNPs however, are able to provide phenotypic information for individual identification and allow inferences to be made on hair and eye colour as well as ancestry and lineage to potentially help identify new suspects or narrow down a large list of suspects (11, 12). This study aimed to generate a set of six informative SNPs that form the IrisPlex (8) from trace material encountered in forensic science.

Single hairs and fragments of fingernails were selected for this study. Both sample types are notoriously difficult to obtain meaningful nuclear DNA due to low initial template DNA, the large variation in extraction methods used, and the poor efficiency of extraction methods (13-17). Direct PCR, where the sample of interest is placed directly into the amplification reaction, has the benefit of no loss of DNA template and therefore provides a potential increase in relative sensitivity compared to performing a DNA extraction. There have been recent reports on using direct PCR for a range of substrates using STR typing (13, 18-22) and here we report on applying direct PCR to the generation of phenotypically informative SNPs on a single hair and a fragment of fingernail.

2. Materials & Methods

2.1 Samples

Five donors (three female and two male) provided five recently plucked hairs and five fingernail clippings each. This generated a total of 50 samples comprising 25 anagen hairs and 25 nail clippings to be used in this experiment. The collection of samples was in line with approval from the Southern Adelaide Clinical Human Research Ethics Committee. The growth phase of the hairs were determined by microscopy. Fingernails were collected by the donor within 15 minutes post hand-washing or showering.

2.2 DNA Extraction from buccal swabs

Buccal swabs were provided to allow comparison to the reference SNP profile of the donors. DNA was isolated from buccal swabs using a QIAGEN® Mini kit (Qiagen) following the manufacturer's protocol and eluted into a final volume of 100 µL. The DNA was quantified using a Qubit® 2.0 Fluorometer (Life Technologies, Victoria, Australia) following manufacturer's recommended protocol. From these extracts 1 ng was used in the PCR.

2.3 Direct PCR from hair and fingernails

Direct PCR was conducted by removing approximately 5 mm of proximal tip of the hair or approximately 4 mm^2 of each fingernail clipping, using sterile scissors and tweezers. The single hair and single nail fragments were placed into separate 0.2 mL thin walled tubes. The tubes contained 12 µL of the IrisPlex primer mix for 6 SNPs (using the same primer concentrations as published) (8) and 12 µL of PCR master mix from the QIAGEN® multiplex PCR kit (Qiagen, Victoria, Australia) making a total volume of 24 µL.

2.4 Amplification of SNPs

The amplifications were conducted in a GeneAmp® System 9600 thermal cycler (Life Technologies) using the recommended protocol (95 °C for 15 mins, followed by 94 °C for 30 sec, 61 °C for 90 sec, 72 °C for 60 sec, and 60 °C for 30 mins) with the exception of a decrease in cycle number. The standard 33 cycles was decreased to 31 cycles for direct samples based on previous knowledge of over-amplification of these sample types (13, 15, 23). The standard IrisPlex protocol was followed for the remaining SNP steps (8), which includes: cleaning 5 µL of PCR product with 2 µL of ExoSAP-IT and incubating at 37 °C for 45 min followed by 80 °C for 15 min; SBE reaction with 3 µL of combined SBE primers, 1 µL of SNaPshot™ multiplex reaction mix, and 1 µL of cleaned PCR product amplified at 96 °C for 2 mins, followed by 25 cycles of 96 °C for 10 sec, 50 °C for 5 sec and 60 °C for 30 sec; SBE cleanup using 1 µL of added SAP to the SBE PCR product

and incubating at 37 °C for 45 min followed by 75 °C for 15 min; capillary electrophoresis of cleaned SBE product was performed on an ABI 3130*xl* Genetic Analyser (Life Technologies) using POP-4™ polymer (Life Technologies).

2.5 Analyses of data

The data were analyzed using GeneMapper® v3.2 (Life Technologies). The detection threshold was set at 50 relative fluorescence units (RFU).

3. Results

Full IrisPlex SNP profiles were obtained from 100 % of the 25 single hair samples and 10 of the 25 (40 %) of fingernail samples (Table 1). Additionally, 7 of the 25 (28 %) fingernail SNP profiles displayed all SNP alleles except for 1 or 2 alleles that exhibited drop-out. This is typical of insufficient template DNA and might be expected from some fingernail fragments. A full profile from a fingernail clipping and single hair matching the donor profile can be observed in Figure 1. Only eight of the fingernail samples failed to generate any SNP alleles. The eight failed profiles were all from two of the five participants, suggesting that these individuals may have a lower propensity to load their hands with DNA, or a poor 'shedder' status.

All SNP profiles obtained from hairs and fingernail clippings matched the SNP profile of each individual's reference profile. There were no observations of allelic drop-in or contamination in any of the 42 SNP profiles obtained.

4. Discussion

We have demonstrated that SNP profiles can be generated routinely from a both a single hair and from a fragment of a fingernail. Nuclear STRs are infrequently obtained from a single hair when subjected to DNA extraction prior to amplification and therefore mitochondrial DNA typing is often

used. The SNPs used in this test where all 25 hairs generated a full SNP profile are all nuclear-based indicating the possibility of gaining an informative SNP profile from such single hair.

Of the 25 nail clippings, 17 generated SNP profiles containing information at at least four loci. Given that the nails were collected from donors post hand-washing or showering, a question arises as to the source of the DNA. In all cases the SNPs from the fingernails matched that of the donor with no additional alleles indicating that the DNA came from cellular material intrinsic to the nail itself or shed from the skin of the donor.

When using direct PCR there is a reduction in time and costs by omitting the extraction step and there is no loss of DNA during the extraction process, allowing these samples to be processed successfully to obtain SNP profiles of a forensic standard. As direct PCR only requires a small sample, such as a 4 mm^2 section of fingernail, typically there will be enough material to attempt multiple, direct PCRs or a standard extraction when initial direct PCR did not yield sufficient results. This may be important in jurisdictions where there is a requirement of secondary testing. Only necessary minimal alteration at the PCR amplification stage of the validated IrisPlex methodology occurred to ensure that the forensic science community could adopt the process readily. Preliminary studies using the same sample types with the SNP*for*ID 34-plex ancestry test (24) have also shown promising results within our laboratory, indicating the great potential for the use of direct PCR in the field of forensically informative SNPs.

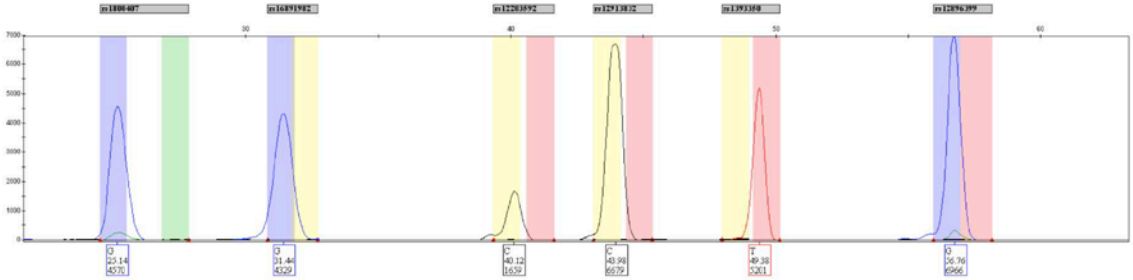
Hair Sample



Nail Sample

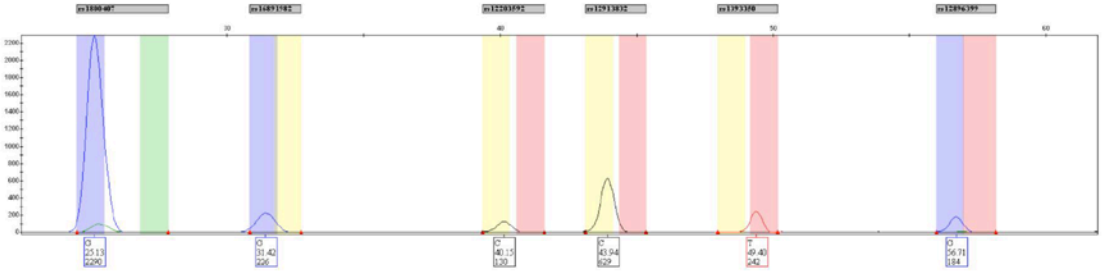


Figure 1 Chromatograms of nuclear DNA from a positive control, single anagen hair root, and a fingernail clipping from one individual. Samples amplified using the IrisPlex SNP procedure at 31 cycles on a GeneAmp® System 9600 thermal cycler and separated on a 3130*xl* Genetic Analyzer.

7.3 Applications

Section 7.2 outlines the successful direct amplification of two human substrates with IrisPlex SNPs and promising results with the SNP*for*ID 34-plex ancestry test. A natural progression of research would be to expand on the number and type of SNP panels used with a direct PCR approach, such as the more recent HIrisPlex panel [14] that determines hair colour as well as eye colour, and the vast amount of individual identification SNPs available [8, 15-17], including the SNP*for*ID 52-plex panel [13, 18, 19]. Of course, human hair and fingernails are not the only substrates that can be amplified directly: fibres from clothing, fibres from swabs used on a range of surfaces, as well as tape used in tape lifting fabrics, could also be investigated in conjunction with SNP testing.

There are an increasing number of forensic informative SNPs being discovered, and the SNaPshot® multiplex kit can only incorporate the use of 30 – 50 SNPs in a single assay [20-23]. The drive to obtain more information from a single sample is leading to the combination of ancestry and phenotypic informative SNPs through the means of next generation sequencing (NGS), where thousands of genetic markers can be genotyped simultaneously [24-27]. As NGS technology continues to develop and improve, the systems will be able to combine different forensic assays to accommodate the new SNP markers that are continually being discovered. Less input DNA is required for NGS, and if coupled with direct PCR techniques, could lead to great improvements when processing difficult trace evidence and degraded samples.

7.4 Concluding Remarks

The results from this study highlight the potential use of DNA trace samples as a source for directly amplifying forensic informative SNPs. A wide range of substrates and SNPs can be combined to further increase the likelihood of obtaining profiles from degraded and challenging samples. As the number of forensic informative SNPs continues to grow, newer technologies such as NGS are being implemented to provide incredible amounts of data from single samples. By combining individual identification SNPs, ancestry inference SNPs, and phenotypic inference SNPs into one process, the application of data can be applied to a widening range of investigations such as missing persons, DVI scenarios, and the inclusion or exclusion of suspects or victims to assist an investigation.

Introduction

We report on the successful direct amplification of **IrisPlex** SNP markers using single hair follicles and fingernail clippings. The use of phenotypic SNPs in forensic science is fast becoming popular due to the nature of the information provided. Standard STR profiles may not be of much significance if there is no reference profile or existing profile on a database for comparison. Phenotypic SNPs have the potential ability aid in inclusion or exclusions of suspects or victims where no other information is available. In this study, we aimed to determine if SNPs could be amplified using direct PCR from single hair follicles. We chose to amplify SNPs from the validated IrisPlex system, an informative tool for determining eye colour. A section (~ 5 mm) of hair from the proximal tip, and sections of fingernail clippings (~ 2 mm^2) was used separately in the initial PCR amplification. All following steps adhered to the IrisPlex protocol [1]. Profiles obtained from the hairs and nails consistently matched the reference profiles of the individuals tested. The results from this study highlight the potential use of DNA trace samples as a source for directly amplifying informative SNPs.

Method

- **Samples** A total of 25 anagen hairs from 5 (male and female) donors were analysed. Growth phase was determined using microscopy. Additionally, 25 fingernail clippings were also processed from the same donors. DNA extracts from buccal swabs were provided as references of donors. A total of 50 samples used in this experiment.
- **Direct PCR** was conducted by removing approximately 5 mm of the hair proximal tip or ~ 2 mm^2 of each fingernail clipping, using sterile scissors and tweezers. The hair and nail fragments were placed into separate 0.2 mL thin walled tubes in a volume of 24 µL of PCR mix using IrisPlex primer sets for 6 SNPs and QIAGEN multiplex buffer. IrisPlex protocols followed for remaining SNP steps.
- **Amplification** was conducted in a GeneAmp® System 9600 thermal cycler (Life Technologies) using the recommended protocol. The standard 33 cycles was decreased to 31 cycles for direct samples.
- **Analysis:** Samples were run on an ABI 3130*xl* Genetic Analyser (Life Technologies) following standard procedures. The data were analysed using GeneMapper® v3.2. The detection threshold was set at 50 relative fluorescence units (RFU).

Results

- A full profile was obtained from 100% of anagen hair samples and 40 % of fingernail samples. Additionally, 28 % of fingernail SNP profiles displayed all SNP alleles except for 1 or 2 (drop-out).
- As each fingernail sample only required a 2 mm^2 section, additional testing either by direct PCR or standard extraction methods can be carried out if required on samples that did not yield results.

Table 1. Summary of SNP profiles obtained using direct PCR with fingernail and hair samples. Total n = 50.

	SNP Profile Obtained		
Sample Type	**Full Profiles (All 6 SNPs)**	**Partial Profiles (drop out ≤ 2 alleles)**	**No Results (zero alleles obtained)**
Fingernail Clipping	40 % (n = 10)	28 % (n = 7)	32 % (n = 8)
Anagen Hair Fragment	100 % (n = 25)		
Total	**n = 35**	**n = 7**	**n = 8**

Results

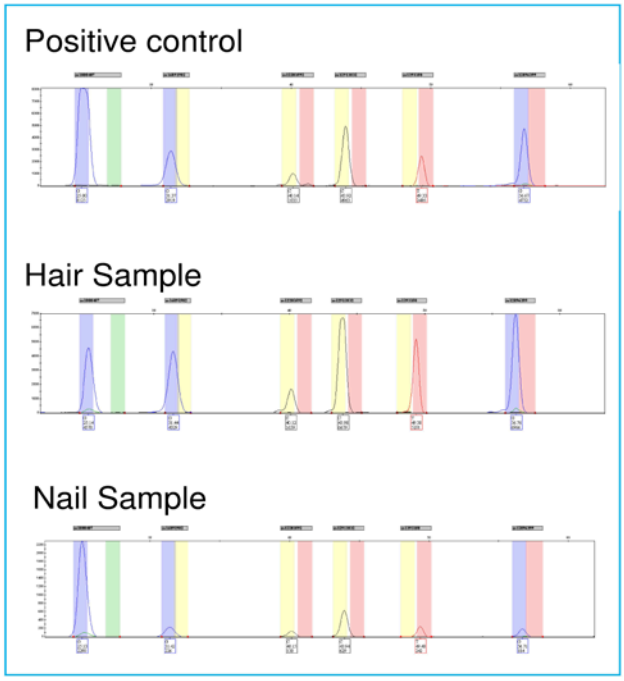

Figure 1. Chromatogram of nuclear DNA from single **anagen** hair root, and **fingernail** clipping, amplified using IrisPlex SNP procedure at 31 cycles on a GeneAmp® System 9600 thermal cycler.

Concluding Remarks

- DNA extraction was not required to obtain SNP profiles to a forensic standard.
- Complete SNP profiles were obtained from 100 % of anagen hair samples, and 40% of fingernail samples.
- Allelic drop-in or contamination was not observed in any of the 42 SNP profiles obtained from any of the hair or nail samples.
- This method is cost-effective and time saving in forensic casework.
- Additional testing either by direct PCR or standard extraction methods can be carried out if required on nail samples that did not yield results.

ABSTRACT

The IrisPlex system is a DNA-based test system for the prediction of human eye colour from biological samples and consists of a single forensically validated multiplex genotyping assay together with a statistical prediction model that is based on genotypes and phenotypes from thousands of individuals. IrisPlex predicts blue and brown human eye colour with, on average, >94% precision accuracy using six of the currently most eye colour informative single nucleotide polymorphisms (HERC2 rs12913832, OCA2 rs1800407, SLC24A4 rs12896399, SLC45A2 (MATP) rs16891982, TYR rs1393350, and IRF4 rs12203592) according to a previous study, while the accuracy in predicting non-blue and non-brown eye colours is considerably lower. In an effort to vigorously assess the IrisPlex system at the international level, testing was performed by 21 laboratories in the context of a collaborative exercise divided into three tasks and organised by the European DNA Profiling (EDNAP) Group of the International Society of Forensic Genetics (ISFG). Task 1 involved the assessment of 10 blood and saliva samples provided on FTA cards by the organising laboratory together with eye colour phenotypes; 99.4% of the genotypes were correctly reported and 99% of the eye colour phenotypes were correctly predicted. Task 2 involved the assessment of 5 DNA samples extracted by the host laboratory from simulated casework samples, artificially degraded, and provided to the participants in varying DNA concentrations. For this task, 98.7% of the genotypes were correctly determined and 96.2% of eye colour phenotypes were correctly inferred. For Tasks 1 and 2 together, 99.2% (1875) of the 1890 genotypes were correctly generated and of the 15 (0.8%) incorrect genotype calls, only 2 (0.1%) resulted in incorrect eye colour phenotypes. The voluntary Task 3 involved participants choosing their own test subjects for IrisPlex genotyping and eye colour phenotype inference, while eye photographs were provided to the organising laboratory and judged; 96% of the eye colour phenotypes were inferred correctly across 100 samples and 19 laboratories. The high success rates in genotyping and eye colour phenotyping clearly demonstrate the reproducibility and the robustness of the IrisPlex assay as well as the accuracy of the IrisPlex model to predict blue and brown eye colour from DNA. Additionally, this study demonstrates the ease with which the IrisPlex system is implementable and applicable across forensic laboratories around the world with varying pre-existing experiences.

1. Introduction

The field of forensic genetics is making great strides with the rapid scientific and technological evolution in obtaining new knowledge and creating innovative tools for solving crimes more and more effectively. Forensic DNA Phenotyping (FDP), a nascent advancement in this field, is one example of recent innovative developments in forensic genetics and involves the prediction of an individual's externally visible characteristics (EVCs) using biological samples obtained at a crime scene or from an anonymous body (parts) that may belong to a missing person [1–4]. Conventional DNA identification involves the comparison of DNA profiles derived from short tandem repeat (STR) marker genotypes obtained from evidence and reference samples, which is useful in cases when the sample donor is known from their DNA profile. In certain circumstances, sample donors may not be identified, i.e. a match (or familial match) of the DNA profiles with known suspects such as those in criminal offender DNA (profile) databases or with ante-mortem samples in cases of missing persons is not successful, or when DNA profile comparisons with putative relatives of missing persons does not reveal the degree of similarities indicating biological relationship. In these situations, FDP can be used to help investigative authorities focus their search for unknown suspects or missing persons towards individuals with particular DNA-predicted externally visible phenotypes. The DNA-based prediction of EVCs can thus aid investigations by police and other authorities by reducing the number of possible suspects or other individuals if conventional STR typing of the evidence fails to produce identification [1,2]. Furthermore, reconstructing appearance information from biological samples such as bones or teeth or other remains of deceased individuals is relevant in anthropological research disciplines including those relying on ancient DNA analysis [1,2,5].

Several model-based approaches, amongst others [4,6], have been developed for predicting a particular phenotype from DNA most notably human eye (iris) colour [7]; the IrisPlex system is one such tool [8]. IrisPlex can accurately predict blue and brown eye colour with a precision of >94%, according to a previous study [9], using six of the most informative eye colour markers: rs12913832 (HERC2), rs1800407 (OCA2), rs12896399 (SLC24A4), rs16891982 (SLC45A2 (MATP)), rs1393350 (TYR) and rs12203592 (IRF4) in a single genotyping assay and a prediction model based on thousands of individuals for which IrisPlex genotype and eye colour phenotype data are available [7,8,10]. The 94% accuracy is based on using a threshold of $p > 0.7$, however it is possible to use IrisPlex prediction with a lower $p > 0.5$ threshold. The assessment of precision accuracy is based on a broad European dataset of >3800 individuals using IrisPlex can be found in Table 3 of that publication [9]. The IrisPlex assay represents the first FDP system that successfully underwent developmental validation using the Scientific Working Group on DNA Analysis Methods (SWGDAM) guidelines for use in forensic casework [10]. The IrisPlex prediction model, first established on thousands of Dutch Europeans, has been evaluated in several populations within and outside Europe and was shown to perform reliably, independent of the bio-geographic origin of the individual tested [9,11].

In an international effort to test the reliability and consistency of the IrisPlex system for eye colour prediction through an inter laboratory exercise, the European DNA Profiling (EDNAP) Group, a working group of the International Society for Forensic Genetics (ISFG), carried out a collaborative study led by the Department of Forensic Molecular Biology of the Erasmus University Medical Center Rotterdam (Netherlands), who initially developed and validated the IrisPlex system [8–10] and for this reason were chosen to conduct this further assessment on the IrisPlex tool alone. Of the 21 participating laboratories, 18 were from Europe,

2 were from Australia and 1 was from the U.S.A. The prime aim of this exercise was to implement the method and assess the performance of the system across different forensic laboratories with varying levels of experience, from complete novices with no SNP typing experience to participants with SNaPshot experience and those with specific IrisPlex experience.

Notably, some authors previously raised issues about marker content and model outcomes of the IrisPlex system [12–15]. The present collaborate EDNAP exercise, however, represents a rather technical exercise to test the performance of the IrisPlex system across laboratories with varying levels of pre-existing experience. Therefore, issues about marker and model choice for predicting eye colour from DNA may be addressed in more dedicated future studies. Here, we present the results of this collaborative EDNAP exercise, placing emphasis on the reliability and consistency in using the IrisPlex system for blue and brown eye colour prediction from DNA.

2. Materials and methods

2.1. Samples and materials provided to the participating laboratories

The organising laboratory (Department of Forensic Molecular Biology, Erasmus MC University Medical Center Rotterdam, Netherlands) divided the entire exercise into three different tasks. All participants were provided with a detailed written laboratory protocol [8] as well as the eye colour prediction model that is an interactive excel spread-sheet as published earlier [10]. Furthermore, for assay interpretation guidelines, participants were given a protocol stating a 50 relative fluorescent units (rfu) peak height threshold should be used for allele calls using the IrisPlex specific GeneMapper software (Applied Biosystems) Bin and Panel set provided. For a broader understanding of average peak heights and balance ratios, participants were asked to refer to the previous developmental validation publication of the IrisPlex system [10]. In addition to the samples and the primers provided for each task, all reagents, which include: 1× PCR buffer, 2.7 mM $MgCl_2$, 200 mM of each dNTP, 0.5 U AmpliTaq Gold Polymerase, SNaPshot™ Multiplex chemistry for the single base extension (SBE) reactions (Applied Biosystems, Foster City, CA), Exonuclease Shrimp Alkaline Phosphatase (ExoSAP-IT), and Shrimp Alkaline Phosphatase (SAP) (USB Corporation, Cleveland, OH), required for running the IrisPlex system were shipped on dry ice to each of the 21 participating laboratories. The laboratories were asked to use their own internal sizing standard (LIZ 120) and formamide for the capillary electrophoresis run.

Due to an ExoSAP-IT™ degradation issue noted during the early phase of the exercise, which subsequently was acknowledged by the producing company as a bad batch of enzyme, aliquots of a newly delivered and tested ExoSAP-IT™ were shipped again to the requesting laboratories, while the others opted to use their in-house standard cleaning protocols. As this was a clean-up procedure, it did not impede on the testing of the IrisPlex assay overall. Purified products were run by the laboratories using their in-house Genetic Analysers (for type, see Table 1) and analysed with the previously published eye colour prediction model [10] provided by the organising laboratory for predicting human eye colour from IrisPlex genotypes.

As a disclaimer for the choice of samples used in this assessment, please note that it is well established and documented [7,9,16,17], that the IrisPlex system through its use of six eye colour associated SNPs performs very well in predicting blue and brown eye colour with Area Under the receiving operator Curve (AUC) values >0.9; however its use for predicting intermediate eye colour (current AUC of ~0.7) is not at an optimum level yet. This is due to the current lack of knowledge on DNA predictors for these non-blue, non-brown eye colours i.e. green eye colour, individuals with heterochromia etc. which is not only a limitation of the IrisPlex but of all currently available DNA test systems for eye colour [4,6]. DNA variants with similarly high prediction effects on non-blue/brown eye colours as the IrisPlex SNPs have on blue and brown eye colour have yet to be identified. Therefore, the IrisPlex system was previously promoted for the prediction of blue and brown eye colours and thus the organising laboratory opted to test variations in blue and brown eye colour alone for Tasks 1 and 2 to evaluate the current IrisPlex system assay and prediction performance on these categories. Task 3 however incorporates all three categories as this task was based on samples provided by the participating laboratories who were not asked to focus on blue and brown eye colour alone when selecting their Task 3 volunteers.

Tasks 1 and 2 contain samples from individuals of European (80% per task) and non-European bio-geographic origin (20% per task) including one admixed individual in Task 1. The individuals used in Task 3, including information about their bio-geographic background, were at the discretion of the participating laboratories and were unknown to the organising lab.

2.2. Task 1 – IrisPlex eye colour prediction from biological samples with eye colour knowledge

The organising laboratory provided all participating laboratories with five blood samples (labelled Ind1–Ind5) and five saliva

Table 1
DNA extraction and quantification protocols used by the 21 laboratories for both Tasks 1 and 2. Grey boxes indicate no data received from the participating laboratory.

samples (labelled Ind6–Ind10) on FTA cards of 10 individuals with blue ($N = 5$) or brown ($N = 5$) eye colour. To produce these samples, fresh venous blood and saliva samples were collected from ten different individuals and 100 μL of each of the samples were pipetted on to the FTA cards. A digital eye image from each of these 10 individuals who donated blood or saliva was also provided to the participants. All the laboratories were instructed to use their own in-house DNA extraction and quantification protocols. All participating laboratories were asked to generate the IrisPlex genotype profile from each of the 10 samples and using the provided IrisPlex prediction model, to conclude the eye colour prediction of the 10 donor individuals by noting the probability and precision accuracy per each sample and individual using the guidelines implemented in a previous publication [9] as provided to the participants. An example report was also provided to each laboratory to ease the fill-out for return. As the participants were provided with eye pictures, they already knew the eye colour of the study individuals of Task 1 before analyses. However, the conclusion of the eye colour phenotypes had to be based on the genotypes determined by each individual laboratory considering the probability and precision accuracy guidelines provided by the organising laboratory. The term 'precision accuracy' relates to the previous publication [9], which undertook a study on the final prediction called by the IrisPlex model in terms of probability values on over 3800 European individuals. It assesses the highest probability value (which is defined as the eye colour of the individual) and how correct the eye colour prediction was at thresholds that increase in increments of 0.05p; from no threshold to $p > 0.95$ [9].

2.3. Task 2 – IrisPlex eye colour prediction from DNA of simulated casework samples without eye colour knowledge

The laboratories were provided with five DNA samples extracted from simulated casework samples (labelled CW1–CW5) from 5 individuals with blue ($N = 2$) or brown ($N = 3$) eye colour. DNA samples were extracted by the organising laboratory with the QIAamp DNA mini kit (Qiagen, Hagen, Germany). The following biological materials were used for DNA extractions: 2 buccal swabs (CW1 and CW2) – both samples subjected to UV radiation using the Bio-Link (Vilber Lourmat) for 1 min at a strength of 50 J/cm^2 before DNA extraction; saliva on glass slide (CW3) stored at room temperature for 1 week before DNA extraction, whole blood on glass slide (CW4) stored at room temperature for 1 week before DNA extractions, and semen DNA extracted from a frozen donated sample (CW5). DNA concentrations were measured using the nanodrop system and 3 μL of the following solutions were provided: CW1: 0.5 ng/μL, CW2: 0.1 ng/μL, CW3: 0.25 ng/μL, CW4: 2 ng/μL, and CW5: 50 ng/μL (see Table 2 for overview). The samples CW1–CW4 were freshly extracted, quantified and run using the IrisPlex system prior to DNA degradation, thereby serving as a control to their degraded counterparts. In contrast to Task 1, in Task 2 the laboratories were not provided with any eye colour phenotype information of the sample donors. Participants were also not provided with any other sample information such as DNA concentration or treatment prior to DNA extractions of the DNA extracts they received for Task 2. They were asked to generate the IrisPlex genotype profile for each individual and report back the obtained eye colour probabilities and accuracies using the model and materials provided, and to finally conclude the most likely eye colour category per individual. An example report was also provided.

Table 2
Details of the simulated casework samples provided to the participating laboratories for the Task 2.

Sample #	Sample type	Treatment	Concentration (ng/μL)
CW1	Buccal Swab	UV for 1 min	0.5
CW2	Buccal Swab	UV for 1 min	0.1
CW3	Saliva on Slide	RT for 1 week	0.25
CW4	Blood on slide	RT for 1 week	2
CW5	Semen	–	50

2.4. Task 3 – participant-driven IrisPlex eye colour prediction

This part of the study was optional. Each participating laboratory was instructed to collect and genotype samples from five different individuals of any eye colour. Selection of volunteers and biological materials was at the discretion of the participants. An important caveat in this task is that IrisPlex cannot guarantee a high prediction accuracy of the non-blue and non-brown eye colours; however, in contrast to Tasks 1 and 2 no eye colour phenotype restrictions were imposed on the participants in their choice of volunteers for Task 3. The laboratories were asked to report the DNA concentration, IrisPlex genotypes, eye colour probability outcomes and accuracy percentages, and a digital high-resolution eye image of the genotyped individuals. The organising laboratory instructed that the iris photo should be taken in natural light conditions (no fluorescent bulb light) with and without flash lens using a digital camera focusing on eyes only (no full portrait).

3. Results and discussion

3.1. Sample extractions and quantifications by each participating laboratory

As the DNA extraction and quantification method can influence genotyping outcomes due to the quality and quantity of DNA extracted and consequently input into a downstream reaction, it can thus influence phenotype inference from the genotypes produced in FDP systems. Therefore we included extraction and quantification monitoring in this exercise. As part of Task 1, the host laboratory provided the participating laboratories with biological samples (blood and saliva samples on FTA cards) from which the participants extracted and quantified DNA using their methods of choice. To note, the affiliated laboratory number in the author list does not represent the laboratory number described throughout the paper. Protocols used for DNA extraction and quantification were different and are listed in Table 1. As evident, the different extraction and quantification methods used by the participating laboratories provided varying results, as summarised in a box plot diagram (Fig. 1), even though the same volume of biological sample was provided to each of the participants on FTA cards. Labs #2, 4, 13, 14 and 17 used the Qiagen EZ1 investigator kit for extraction and reported on average higher quantification values as compared to Labs #6, 9, 10, 12 and 15 that used the Qiagen QIAamp DNA mini kit extraction protocol. Lab #20 applied a Phenol–Chloroform extraction approach, which yielded on average higher quantification values compared to all the other methods used. Lab #18 used the Prepfiler Forensic DNA extraction kit and obtained on average higher final DNA amounts than all other methods, except Phenol–Chloroform. Labs #5, 7, 8, and 19, which used the Chelex extraction protocol, reported comparatively lower quantification values than all other methods used in this exercise. Worthy to note, this figure assumes that all laboratory input DNA volumes were similar (i.e. the recommended 1 μL). The precise extraction volumes used by all labs were not available to the organising laboratory. This figure merely represents the differing extraction methods yielding varying final DNA concentrations, however, it is expected that the participants followed all recommendations provided by the organising lab which specifically states a 1 μL volume with at least a concentration of 32 pg

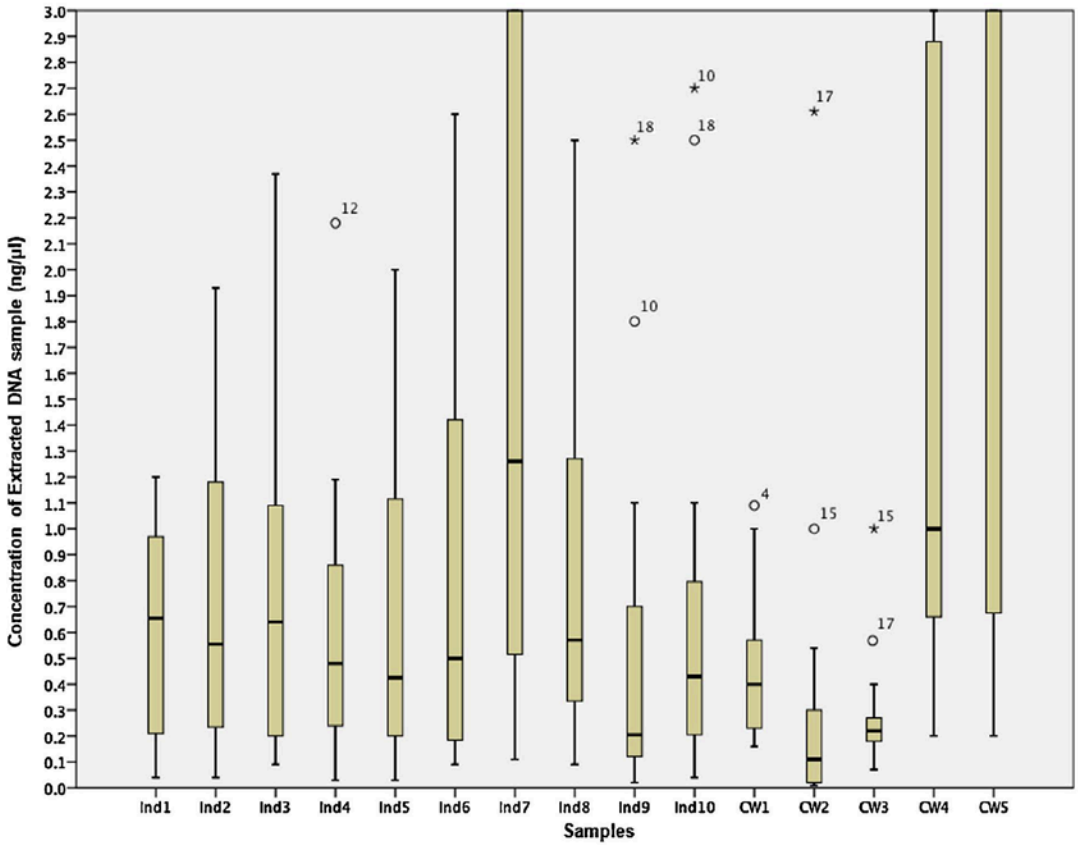

Fig. 1. Box-plot (scaled to 3 ng/µL) showing the variation in obtained DNA concentrations using different methods for extraction and quantification between the 21 laboratories for the 15 samples used in Task 1 and 2. Note that for Task 1 (samples Ind1–Ind10), biological samples were provided to the participants so that DNA extraction and DNA quantifications were carried out by the participants on the same volumes of biological materials provided on FTA cards, while for Task 2 (samples CW1–CW5) participants were provided with already extracted DNA samples that varied in treatment and DNA concentrations. Medians are represented by the horizontal lines and the boxes depict the 25–75% quartiles. The whiskers represent the minimum and the maximum values. Outliers are marked with the laboratory number where they were reported.

DNA input for IrisPlex profiling. The DNA samples provided for Task 2 were previously extracted by the host laboratory using the QIAamp DNA mini kit (Qiagen). The participating laboratories were requested to measure DNA concentrations using their method of choice and to report back the values. Because different quantification methods were used, the obtained concentration estimates differed (Fig. 1 and Supplementary Table 1), similar to Task 1, even though equal aliquots of the very same DNA solutions per each sample were provided to each of the participants. As evident, sample CW2 was recorded as the most variable (0.01–2.61 ng/µL), which contradicts recorded measurements by the organising laboratory of 100 pg (Fig. 1).

Supplementary material related to this article can be found, in the online version, at doi:10.1016/j.fsigen.2014.04.006.

Overall, the recorded DNA quantification data indicate that all samples shipped, both the biological samples on FTA cards of Task 1 and the extracted DNA samples of Task 2, and remained rather stable during transportation and short-term storage at the participating laboratories. For the impact of the varying amounts of DNA obtained by the participants in Task 1 and the varying DNA concentration measures obtained in Task 2 on genotype and phenotype accuracy, see the specific chapters on Tasks 1 and 2 below. From the DNA quantification data reported by the participating laboratories for the samples used in Task 3 (Supplementary Table 1) it is evident that all the samples genotyped for this portion of the exercise were of reasonable quantity. When conducting genotyping analyses and calling the peaks, the 50 rfu fluorescence threshold was set for calling alleles for a locus in all tasks and samples.

3.2. Task 1 – IrisPlex eye colour prediction from biological samples with eye colour knowledge

All participating laboratories reported the predicted eye colour and their probabilities in the format as requested by the organising laboratory. Fig. 2 depicts the accurate genotype and eye colour phenotype calls for all the ten samples as obtained by the 21 participating laboratories. Supplementary Table 2 lists the genotypes of the ten individuals with their respective eye colour probability and accuracy. Fig. 3 shows the eye colour images of the 10 individuals used in this task.

Supplementary material related to this article can be found, in the online version, at doi:10.1016/j.fsigen.2014.04.006.

Twenty of the 21 laboratories (95%) predicted the eye colour of all 10 individuals included in Task 1 correctly from IrisPlex (Fig. 2; green bars). Overall, 208 (99%) of the 210 samples analysed in this task by all the 21 laboratories were reported with the correct eye colour phenotype prediction. An overview of the samples with incorrect genotypes that were discordant with the organising laboratory is provided in Table 3. Only one laboratory (Lab #3) faced difficulties in concluding the correct eye colour phenotype for two samples (Individual 1 and 10). The phenotype for both

	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21
Individuals	10	10	10	10	10	10	9	10	10	10	10	9	10	10	9	10	10	8	10	10	10
Genotypes	60	60	60	60	60	60	59	60	60	60	60	57	60	60	59	60	60	58	60	60	60
Phenotypes	10	10	8	10	10	10	10	10	10	10	10	10	10	10	10	10	10	10	10	10	10

Fig. 2. Accuracy of the IrisPlex genotype calls (6 SNPs) and the IrisPlex-based eye colour phenotype prediction of the 10 samples provided in Task 1 as reported by each of the 21 participating laboratories. Blue indicates the number of individuals that were correctly genotyped at all 6 IrisPlex SNPs (i.e. for which a correct IrisPlex profile was reported). Red indicates the total number of genotypes across all 6 SNPs and all 10 samples that were correctly reported. Green indicates the number of individual samples for which the correct eye colour phenotype was reported. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of the article.)

individuals was reported as inconclusive, although the correct IrisPlex genotypes were obtained and reported. These two individuals had eye colour probabilities for blue, intermediate and brown of 0.306, 0.142, 0.552 and 0.299, 0.253, 0.448 respectively (Fig. 3(a) and (k)), and did not cause a problem for the other 20 laboratories to conclude the correct brown eye colour for both samples.

Overall, 1253 (99.4%) of the 1260 genotypes generated for the 6 IrisPlex SNPs in the 210 samples analysed by all the 21 laboratories were reported correctly. The 7 (0.6%) incorrect genotypes were reported by 4 laboratories, while 17 participants reported the correct 6-SNP IrisPlex profiles for all 10 samples. Importantly, none of these incorrect genotypes led to erroneous eye colour phenotype predictions being reported. Lab #7 reported an incorrect homozygous genotype T instead of the true heterozygous CT for rs12203592 for Individual 8 due to a dropout of the C allele, since the respective peak was below the 50 rfu threshold. Lab #12 reported discordant heterozygous instead of correct homozygous genotypes for Individual 9 across three markers (rs12913832, rs16891982 and rs1393350). Drop-in of the alleles C, G and T was observed for each of the markers rs12913832, rs16891982 and rs1393350 respectively. However, the DNA concentration for this particular sample was reported by Lab #12 to be very low (0.02 ng/μL), much lower than the concentration obtained by the other

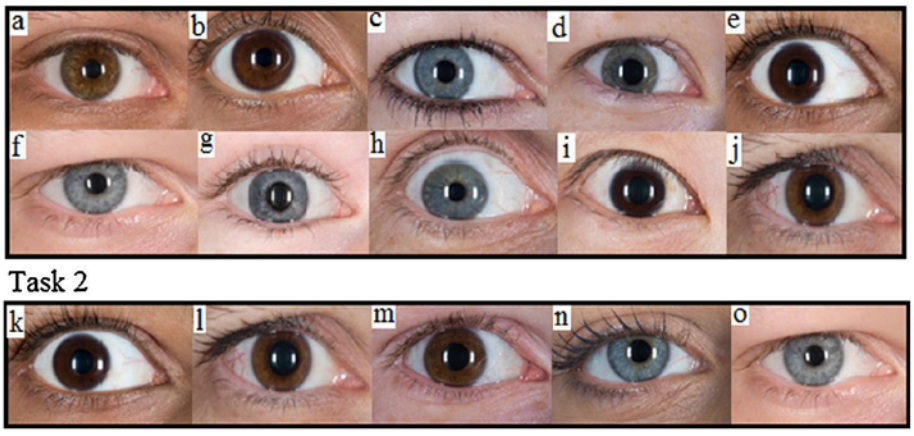

Fig. 3. Eye colour images of the 10 individuals whose samples were used in Task 1 and the 5 individuals whose samples were used in Task 2. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of the article.)

Table 3
Tasks 1 and 2 genotyping results that were discordant between the host and the participating laboratories.

	Sample	Lab#	Locus	Comments
Task 1	Individual 8	7	rs12203592	Drop-out of C
	Individual 9	12	rs12913832	Drop-in of C
	Individual 9	12	rs16891982	Drop-in of G
	Individual 9	12	rs1393350	Drop-in of T
	Individual 2	15	rs16891982	Drop-out of C
	Individual 3	18	rs12203592	Drop-in of T
	Individual 8	18	rs12203592	Drop-out of T
Task 2	CW2	6	rs12913832	Drop-out of T
	CW2	7	rs12913832	Drop-out of C
	CW2	15	rs1393350	Drop-in of T
	CW2, CW3	17	rs12913832	Drop-out of T, C respectively
	CW2	17	rs1800407	Drop-out of A
	CW3	18	rs1393350	Drop-out of T
	CW2	21	rs12896399	Drop-out of T

laboratories for this sample (Supplementary Table 1). In accordance with the provided protocol, 1 μL of DNA solution of this sample was used for the IrisPlex PCR. Therefore, for this sample the amount of DNA input was below the previously established sensitivity threshold of the IrisPlex assay [10], which explains the high failure rate for genotypes of this sample. Lab #15 reported incorrect homozygous genotype of the G allele (instead of the correct heterozygous GC genotype) for individual 2 at rs16891982 due to a dropout of the C allele. Lab #18 experienced at marker rs12203592 a drop-in of allele T for individual 3 and dropout of allele T in individual 8. One explanation could be primer degradation due to incorrect storage of the primer or an incorrect volume addition of this primer to the assay, but unlikely due to a sample issue as the DNA concentrations reported for the individuals 2, 3 and 8 by the Labs #15 and 18 were more than 1.1 ng/μL (provided that the correct input of 1 μL was used). For cases such as these, an erroneous result can be avoided by re-running several analyses of the sample, and is usually recommended when using all genotyping platforms, this includes the IrisPlex system.

3.3. Task 2 – IrisPlex eye colour prediction from DNA of simulated casework samples without eye colour knowledge

In Task 2, the provided five DNA extraction aliquots from simulated casework samples (Table 2) were evaluated by each participating laboratory. Notably, the samples used for DNA extractions not only came from different biological sources (saliva, blood, and semen) but also experienced different environmental conditions (UV radiation, storage at room temperature) and were provided to the participants in varying DNA concentrations (0.1–50 ng/μL), all unknown to the participants. Therefore, and due to the fact that no eye colour phenotypes were provided of the sampled individuals, this task was more challenging than Task 1. Fig. 4 depicts the accurate genotype and eye colour phenotype calls for all the 5 samples as reported by the 21 participating laboratories. Supplementary Table 2 shows the reported genotypes of the five samples with their respective eye colour prediction probabilities and precision accuracy. Fig. 3 shows the eye colour images of the 5 individuals used in this task. An overview of the samples with incorrect genotypes that were discordant with the organising and the other participating laboratories is provided in Table 3.

Eighteen (86%) of the 21 laboratories predicted the eye colour of all 5 individuals correctly from IrisPlex (Fig. 4; green bars). Overall, 101 (96.2%) of the 105 samples analysed by all the 21 laboratories together were reported with the correct eye colour phenotype. The 4 samples (3.8%) for which the eye colour phenotypes were incorrect had been reported by 3 laboratories. Lab #3 predicted the eye colour of 2 of the 5 individuals (CW2 and CW3) as inconclusive, although the genotypes for these samples were reported correctly. Both samples clearly had to be designated as brown from the obtained probabilities ($p = 0.448$ and $p = 0.552$, respectively), and the phenotypes indeed were brown (Fig. 3(l) and (m) respectively), as was correctly interpreted by 18 other laboratories. The other 2 incorrectly phenotyped samples were reported by Labs #6 and 17 due to the drop-out of the T allele at rs12913832 in sample CW2. The 2 laboratories reported an incorrect homozygous C allele instead of a heterozygous CT allele, thereby, reporting an incorrect blue eye colour instead of the correct brown eye colour phenotype (Fig. 3(l)).

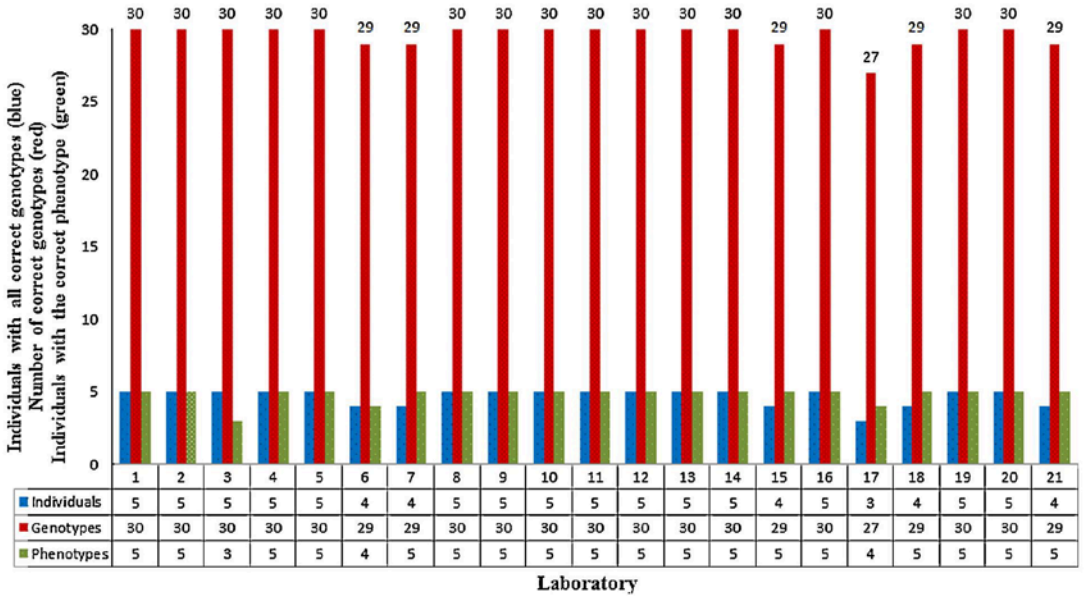

Fig. 4. Accuracy of the IrisPlex genotype calls (6 SNPs) and the IrisPlex-based eye colour phenotype prediction of the 5 samples provided in Task 2 as reported by each of the 21 participating laboratories. Blue indicates the number of individuals that were correctly genotyped at all 6 IrisPlex SNPs (i.e. for which a correct IrisPlex profile was reported). Red indicates the total number of genotypes across all 6 SNPs and all 5 samples that were correctly reported. Green indicates the number of individual samples for which the correct eye colour phenotype was reported. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of the article.)

Overall, 622 (98.7%) of the 630 genotypes generated for the 6 IrisPlex SNPs in the 105 samples analysed by all laboratories together were correctly reported in Task 2. The 8 (1.3%) incorrect genotypes were produced in 2 samples (CW2 and CW3) by 6 laboratories, while 15 of the 21 laboratories (71.4%) reported the correct 6-SNP IrisPlex profile for all 5 samples. In contrast to the 2 (25%) genotype errors in sample CW2 by Lab #6 and 17 that caused phenotype errors as mentioned in the previous paragraph, the remaining 6 incorrect genotypes (75%) did not have any impact on the eye colour phenotype accuracy. At rs12913832, Lab #7 reported an incorrect genotype due to a drop-out of the C allele for sample CW2. A drop-in of the T allele for CW2 and drop-out of the T allele for CW3 at rs1393350 resulted in incorrect genotyping by Labs #15 and 18 respectively. Furthermore, incorrect genotypes were reported by Lab #21 at rs12896399 for sample CW2 due to a drop-out of the T allele. Lab #17 experienced problems in the first typing of samples CW1, 2 and 3 and subsequently retyped these samples in different DNA dilutions. At rs12913832, drop-out of the T allele for CW2 (as mentioned above); drop-out of the C allele for CW3, and drop-out of the A allele at rs1800407 for CW2 were reported which resulted in erroneous results for this laboratory. A dilution step performed by the participating laboratory, due to a misleading quantification result, of the already low quantity degraded samples provides a likely explanation for the drop-out of the alleles in this set of samples.

Several laboratories ($n = 3$; Labs #3, 6 and 17) experienced difficulties with correct phenotyping of the simulated and treated casework samples in Task 2 for which no eye colour phenotypes were provided as opposed to the untreated biological samples provided together with eye colour phenotypes in Task 1 ($n = 1$; Lab #3). Similarly, more laboratories ($n = 6$; Labs #6, 7, 15, 17, 18 and 21) had difficulties in correct genotyping of Task 2 samples in relation to Task 1 samples ($n = 4$; Labs #7, 12, 15 and 18). Within Task 2, the most genotyping and phenotyping difficulties i.e. allelic drop-outs and drop-ins were reported for 2 particular samples (CW2 and CW3). Sample CW2 was reported with different incorrect genotypes by 5 of the laboratories (Labs #6, 7, 15, 17 and 21) and sample CW3 was reported incorrectly by 2 laboratories (Labs #17 and 18) (see Table 3 for overview). Sample CW2 must therefore be noted as being a difficult sample to genotype. From Fig. 1, it is evident that, of the laboratories that reported quantification data for Task 2, sample CW2 was recorded as the most variable (0.01–2.61 ng/μL), which strongly deviates from the recorded measurements by the organising laboratory of 100 pg. Given its unusual quantification range, severe degradation and heterozygosity at 3 (rs12913832, rs1800407 and rs12896399) of the 6 SNPs, increased incidence of allelic drop-out may be expected in sample CW2 as compared to the homozygous sample CW1 (which also experienced UV degradation) that caused no problems for genotyping. This demonstrates, as expected and as also known for any other genotyping assay, that the combination of low quality and low quantity template DNA provides challenges for correct genotyping including for the IrisPlex assay. However, it should be emphasised that 244 of the 252 (96.8%) genotypes of the most challenging samples CW2 and CW3 were generated correctly by 15 of the 21 (71.4%) participating laboratories, which demonstrates the reliability of the IrisPlex assay for difficult DNA samples. This also represents the necessity of employing duplicate analysis when genotyping samples of low DNA quantity in final case work applications.

3.4. Task 3 – participant-driven IrisPlex testing

The optional Task 3 of the exercise, where participants were asked to recruit their own volunteers for IrisPlex genotyping and eye colour prediction, was performed by 20 of the 21 laboratories. Lab #7 could not perform this task due to reported ethical issues. Supplementary Table 3 summarises the data for this task. Based on the digital eye images provided by the participants (Fig. 5), the organising laboratory judged the correct phenotypes by two independent experienced observers. Lab #12 performed this exercise and reported the genotype and phenotype, but provided no eye images to the host laboratory for inspection. As it was not possible to judge the accuracy of the results provided by this participant, they were excluded from the analyses. As can be seen in Fig. 6, 16 of the 19 laboratories (84.2%) predicted the eye colour of all analysed individual samples correctly, while 3 laboratories faced difficulties in concluding the correct eye colour from the estimated probability combinations for some samples. Overall, 96 (96%) of the 100 samples analysed by the 19 laboratories were reported with the correct eye colour prediction, as judged by the organising laboratory based on the digital eye images sent by the participants. The 4 samples reported with incorrect eye colour were from 3 different laboratories (1x#2, 2x#3, and 1x#5). Lab #2 reported blue eye colour ($p = 0.678$) for their sample 1 but the eye image showed brown colour and the estimated brown eye probability was only 0.191 (Fig. 5(a)). Lab #3 obtained the following probabilities for their sample 1: Blue – 0.207, Intermediate – 0.161 and Brown – 0.632 and reported an inconclusive result, while the probability for brown was by far higher than for the other two categories so that brown should have been concluded instead and indeed the respective eye image showed brown (Fig. 5(b)). Sample 4 of Lab #3 appeared blue from the images (Fig. 5(c)) but a high brown eye probability ($p = 0.892$) was obtained while the blue eye probability was low ($p = 0.024$). Lab #5 obtained probabilities of Blue – 0.375, Intermediate – 0.264 and Brown – 0.361 for their sample 1, and reported blue eye colour but the image indicates brown eye colour (Fig. 5(d)). In this case, however, the eye colour could have been reported inconclusive since the brown and the blue eye colour probabilities were very similar. It is therefore important to use and report the level of precision accuracy based on each probability threshold with the final prediction, i.e. $p < 0.5$ highest probability value, $p > 0.5$ highest probability value. This can be found in Table 2 of our previous publication [9]. It is noteworthy to emphasise that the IrisPlex genotypes in Task 3 were not verified independently in contrast to those in Tasks 1 and 2. Therefore we cannot know for sure if any of the 4 incorrect phenotype predictions in Task 3 may have been caused by incorrect genotypes, although the high genotyping accuracy rates achieved in Tasks 1–3 suggest this might be somewhat unlikely. Due to violation of anonymity, the geographic origin of these individuals cannot be determined.

Supplementary material related to this article can be found, in the online version, at doi:10.1016/j.fsigen.2014.04.006.

Further to note, participants for Task 3 were not asked to restrict their choice of volunteers to blue and brown eye colour only. This was different from Tasks 1 and 2 where only volunteers with blue and brown eye colour were used due to known limitations of the IrisPlex system to accurately predict non-blue and non-brown eye colours [8–10]. However only Lab #1 reported 2 individuals as intermediate ($p = 0.411$ and $p = 0.405$) and from the eye images (Fig. 5(e) and (f) respectively), we can confirm that the individuals were correctly predicted as intermediate as they contain substantial pupillary rings of a different colour (i.e. majority of iris blue colour with obvious brown pupillary ring). It is also worth noting that although no restrictions were imposed on the choice of samples for Task 3, all the laboratories (except Lab #1) chose individuals with either blue or brown eyes and hence it is most likely that all the participants were guided by knowledge of (or clearly considered the) limitations of IrisPlex for accurately predicting non-blue and non-brown eye colour phenotypes. Furthermore, according to general knowledge, the frequency of

Fig. 5. Eye images sent by the participating laboratories used for the voluntary aspect of the study, Task 3. Eye images include probability values for blue, intermediate and brown eye colour provided by the participants as determined from the IrisPlex genotypes. The area surrounded by the red lines indicates the incorrect eye colour prediction as assessed by the host laboratory from inspection of the eye images provided, and compared with the eye colour phenotype reported by the participants based on IrisPlex analysis. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of the article.)

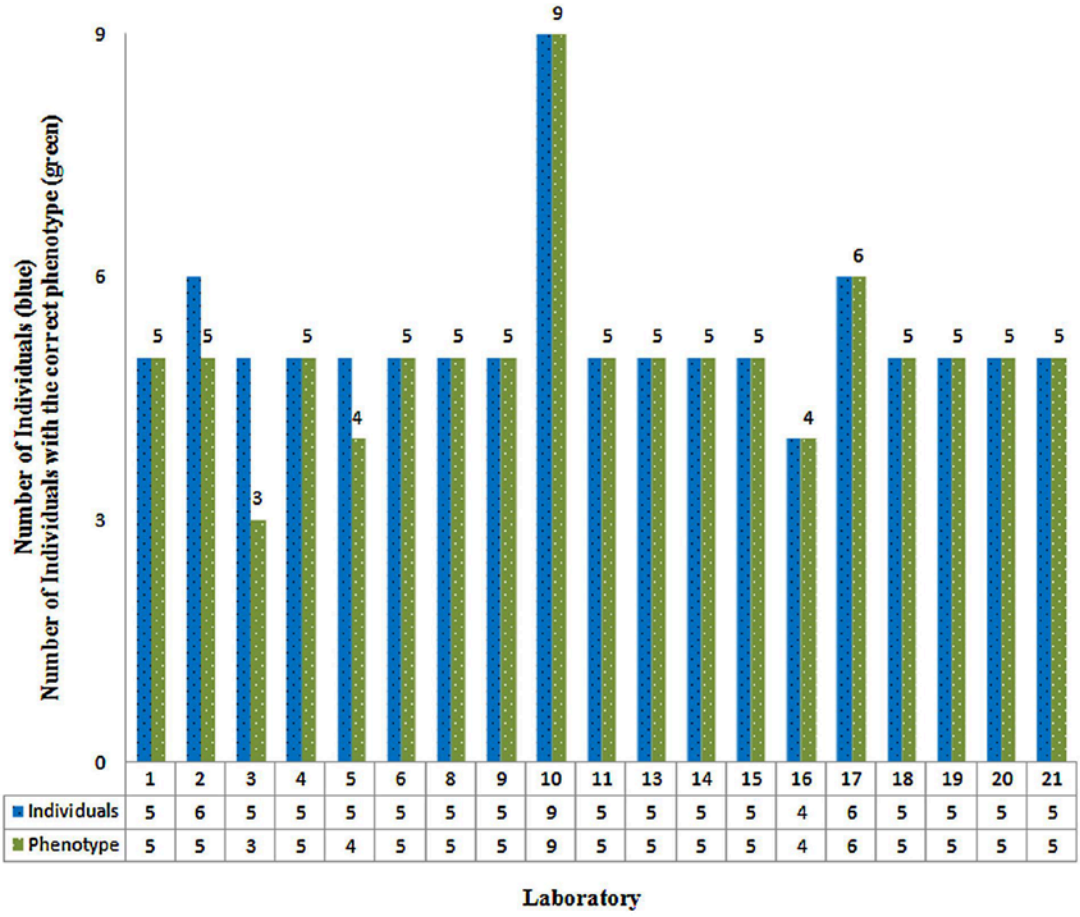

Fig. 6. Accuracy of the IrisPlex-based eye colour phenotype prediction of the samples selected by all 19 laboratories participating in Task 3 (Lab #7 did not participate in this task). Lab #12 though performed the task, did not include images and hence was not considered here. The correct eye colour phenotype was assessed by the host laboratory from inspection of the eye images provided, and compared with the eye colour phenotype reported by the participants based on IrisPlex analysis. Blue indicates the number of individuals that were genotyped and green indicates the number of individuals for which the correct phenotype was reported. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of the article.)

blue and/or brown eyes is comparatively higher than intermediate in the population, which could explain the rarity of volunteers with intermediate eye colour phenotype used in Task 3.

The overall performances of the participating laboratories in all 3 tasks, is shown in Supplementary Table 4.

Supplementary material related to this article can be found, in the online version, at doi:10.1016/j.fsigen.2014.04.006.

4. Conclusions

Overall, the high level of consistency achieved throughout this collaborative effort in all 3 tasks illustrates the reliability of the IrisPlex assay in producing highly accurate 6-SNP genotypes and of the IrisPlex prediction model in producing accurate blue and brown eye colour phenotypes from IrisPlex genotypes. As shown here and previously [8], the IrisPlex assay provides reproducible results despite differing levels of experience of the laboratory personnel involved and differing DNA extraction and quantification methods used. The results obtained in this collaborative exercise demonstrate the robustness and reproducibility of DNA-based eye colour prediction when using the IrisPlex system in different forensic laboratories world-wide. As emphasised before [8–10], future focus shall be placed on improving DNA-based prediction of non-blue and non-brown eye colours, for which the IrisPlex system is less suitable than for blue and brown eye colour prediction from DNA.

Acknowledgements

We would like to thank Gabriela Huber, Nelli Roininen and Mintu Hedman for outstanding technical assistance and Vlastimil Stenzl for support. This work was funded in part by the Netherlands Forensic Institute (NFI) and a grant from the Netherlands Genomic Initiative (NGI)/Netherlands Organization for Scientific Research (NWO) within the framework of the Forensic Genomics Consortium Netherlands (FGCN). Funding for Adrian Linacre and Renee Ottens was provided by the Attorney General's Office, South Australia, for Theresa Gross by the EU 7th Framework Programme (FP7/2007–2013) under Grant Agreement N° 285487 (EUROFORGEN-NoE), and for Antti Sajantila by the Finnish Foundations' Pool Professorship (Paulo Foundation).

CHAPTER 8

Further Applications, Conclusions & Impact

Further Applications, Conclusions & Impact

8.1 Preface

The final chapter of this thesis discusses the rippling effect this research has had within the forensic science community, and the new directions for direct PCR research heading into the future. Given the number of variables a crime scene may produce, as far as the substrates and surfaces DNA may be found on, there are still many more applications of this technique to explore. *Section 8.2* describes these possibilities in depth, highlighting research already trialled and research currently underway. Specifically this section describes: the possibilities of using direct PCR with human teeth and bones, showcasing the preliminary results obtained during this candidature from human teeth samples; discussing the research projects that have been undertaken as a result of this candidature within the Flinders DNA Laboratory; and exploring the world wide use of this technique in other forensic areas such as explosive devices, and wildlife crime.

8.2 Further applications

As mentioned previously, there are many variables to explore using direct PCR, too many to research sufficiently in one candidature. Given the data from this thesis, it is obvious that certain substrates perform better than others due to physical properties and the presence of inhibitors. Keratin-based substrates such as human and animal hair, and human fingernails all consistently provided meaningful data. Keratin does not break down completely during direct PCR; hair and nail samples remain visibly intact after amplification, suggesting that known inhibitors such as melanin are not released into the PCR matrix. This is supported by the data as little to no inhibition is observed. Fibres however, are more difficult to navigate with this technique. There are endless blends and compositions of fibre types, synthetic or natural, as well as dyes. Fibre types and dyes can affect the release of the DNA from the fabric into the PCR matrix, as well as causing complete inhibition of amplification. Fibre variables are too high for direct PCR to produce consistent results when using samples such as clothing. The aim of using direct PCR is to maximise results by utilising all available DNA, and minimise costs by reducing the time spent processing samples for which there is little chance of generating a DNA profile. The data from this thesis can help determine what substrates are going to have beneficial outcomes, and what substrates are unsuitable for implementation.

8.2.1 Human teeth & bones

It is no secret that human bone and teeth are some of the most challenging substrates for DNA extraction and purification. The process is expensive, long and arduous, often requiring specific equipment or even specialised laboratories. The DNA from these samples is often highly degraded, commonly due to environmental exposure, with the composition of bone and teeth creating further challenges [1-4]. The samples must be decalcified in order to remove PCR inhibitors, and release the DNA from the internal matrices. There has been no shortage of research to simplify the process, to minimise the use of specialised and expensive equipment, minimise the use of toxic chemicals, reduce the risks of contamination, as well as maximising the quantity and quality of DNA obtained [5-14].

The successful direct amplification of these substrates would obviously drastically reduce time and costs involved, as well as reduce contamination opportunities, as there are fewer steps in which exogenous DNA could be unintentionally introduced. Similarly to all the substrates tested in this thesis, any DNA on the surface of a substrate would be released into the PCR matrix during the amplification process. Several initial direct PCR amplifications were conducted on human teeth samples during this candidature to assess if this was a viable technique for this substrate type.

Dr Laurence J Henbest of Perfect Smile in Adelaide, South Australia, donated human teeth samples, providing consent for the samples to be used for human identification for forensic science research purposes only. Samples were stored individually in Milton Antibacterial Solution: Hospital Grade (MSDS: 1 % NaOCl - bleach), and then rinsed in ethanol followed by a sterile water wash. Samples were left to dry before processing. The outer layer of the tooth was scraped and cleaned with a disposable scalpel to remove any residual bleach that may cause inhibition, followed by another sterile water wash. To fragment the tooth sample small enough to amplify directly, the tooth was wrapped in Kimwipes™ (Kimberley-Clark®) and then placed in a sterile ziplock bag. This package containing the tooth was then crushed in a clean vice. The crushed tooth was then emptied into a sterile plastic container.

The pulp of the tooth was removed and placed in a 1.5 mL centrifuge tube for extraction, to enable DNA comparison to any tooth fragments. The pulp was extracted using the QIAamp® DNA Micro Kit (Qiagen) following the manufacturer's protocol for tissue extraction. The sample was incubated overnight and eluted in a final volume of 50 µL. The DNA was quantified using a Qubit® 2.0 Fluorometer (Life Technologies).

Direct PCR was conducted by placing powdered tooth sample into a 0.2 mL thin walled tube containing 10 µL of PCR master mix from the AmpFℓSTR® NGM™ kit (Life Technologies, Victoria, Australia) along with 5 µL of the primer mix and 1 µL (5 units) of AmpliTaq Gold® DNA polymerase (Figure 8.1). The addition of the AmpliTaq Gold® DNA polymerase is to increase the overall units of enzyme in the reaction to assist in overcoming inhibitors that may be present on the tooth. A further 9 µL of sterile H_2O were added to make the final volume 25 µL. The amplification was conducted in a GeneAmp® System 9600 thermal cycler (Life Technologies) using the manufacturer's recommended conditions. During PCR, 29 cycles was used for all reactions. The NGM™ kit amplifies 15 STR loci plus the amelogenin locus.

Capillary electrophoresis was performed on an ABI 3130*xl* Genetic Analyser (Life Technologies) using POP-4™ polymer (Applied Biosystems). An aliquot of 1 µL of the PCR sample was added to a solution of 0.5 µL of ABI GeneScan-600 LIZ® Size Standard and 9.5 µL of Hi-Di™ Formamide. Samples were then denatured at 95 °C for 3 min. Electrophoresis was conducted at 3 kV with a 10 s injection. The data were analysed using GeneMapper® v3.2. The detection threshold was set at 50 relative fluorescence units (RFU).

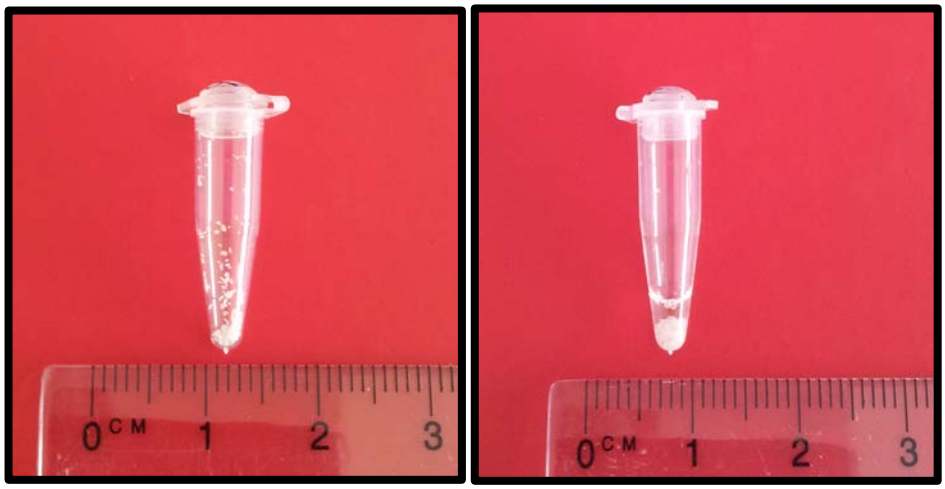

Figure 8.1 – Powdered human tooth sample in 0.2 mL thin walled tube. Left frame shows tooth powder prior to the addition of the PCR master mix, right frame shows the addition of 25 µL of NGM™ kit reagents after brief centrifugation.

Tooth samples were trialled from 13 individuals, targeting different areas of the tooth (such as the root dentine, and the crown enamel) with varying success. The results indicated that tooth itself is not a PCR inhibitor, as DNA profiles could be obtained when directly amplified. Full profiles could be obtained from tooth powder (Figure 8.2), that matched the corresponding tooths pulp DNA profile. Eight samples returned DNA data ranging from just a few alleles to full profiles. Five of these samples returned profiles of five complete loci or more.

Most tooth samples showed signs of over amplification; with high RFU values and the occasional split peaks. Clearly there is opportunity to optimise the methods, and determine the best section of tooth for direct amplification. Due to limitations in time and equipment, tooth as a substrate for direct amplification was not researched further in this candidature. Gaining STR information from forensic samples provides the highest discrimination power in terms of DNA analysis. Teeth and bone samples are often analysed for mitochondrial DNA or SNP information due to degradation factors that make STR information difficult to obtain from these substrates. STR information was successfully generated from teeth samples in this preliminary work when amplified directly. With new forensic SNPs being researched and implemented, teeth and bone samples would make an ideal substrate for direct amplification using SNPs as they amplify smaller fragments than STRs. Further investigation into human teeth and human bone samples using STR and SNP analysis would undoubtedly be a significant research project on its own.

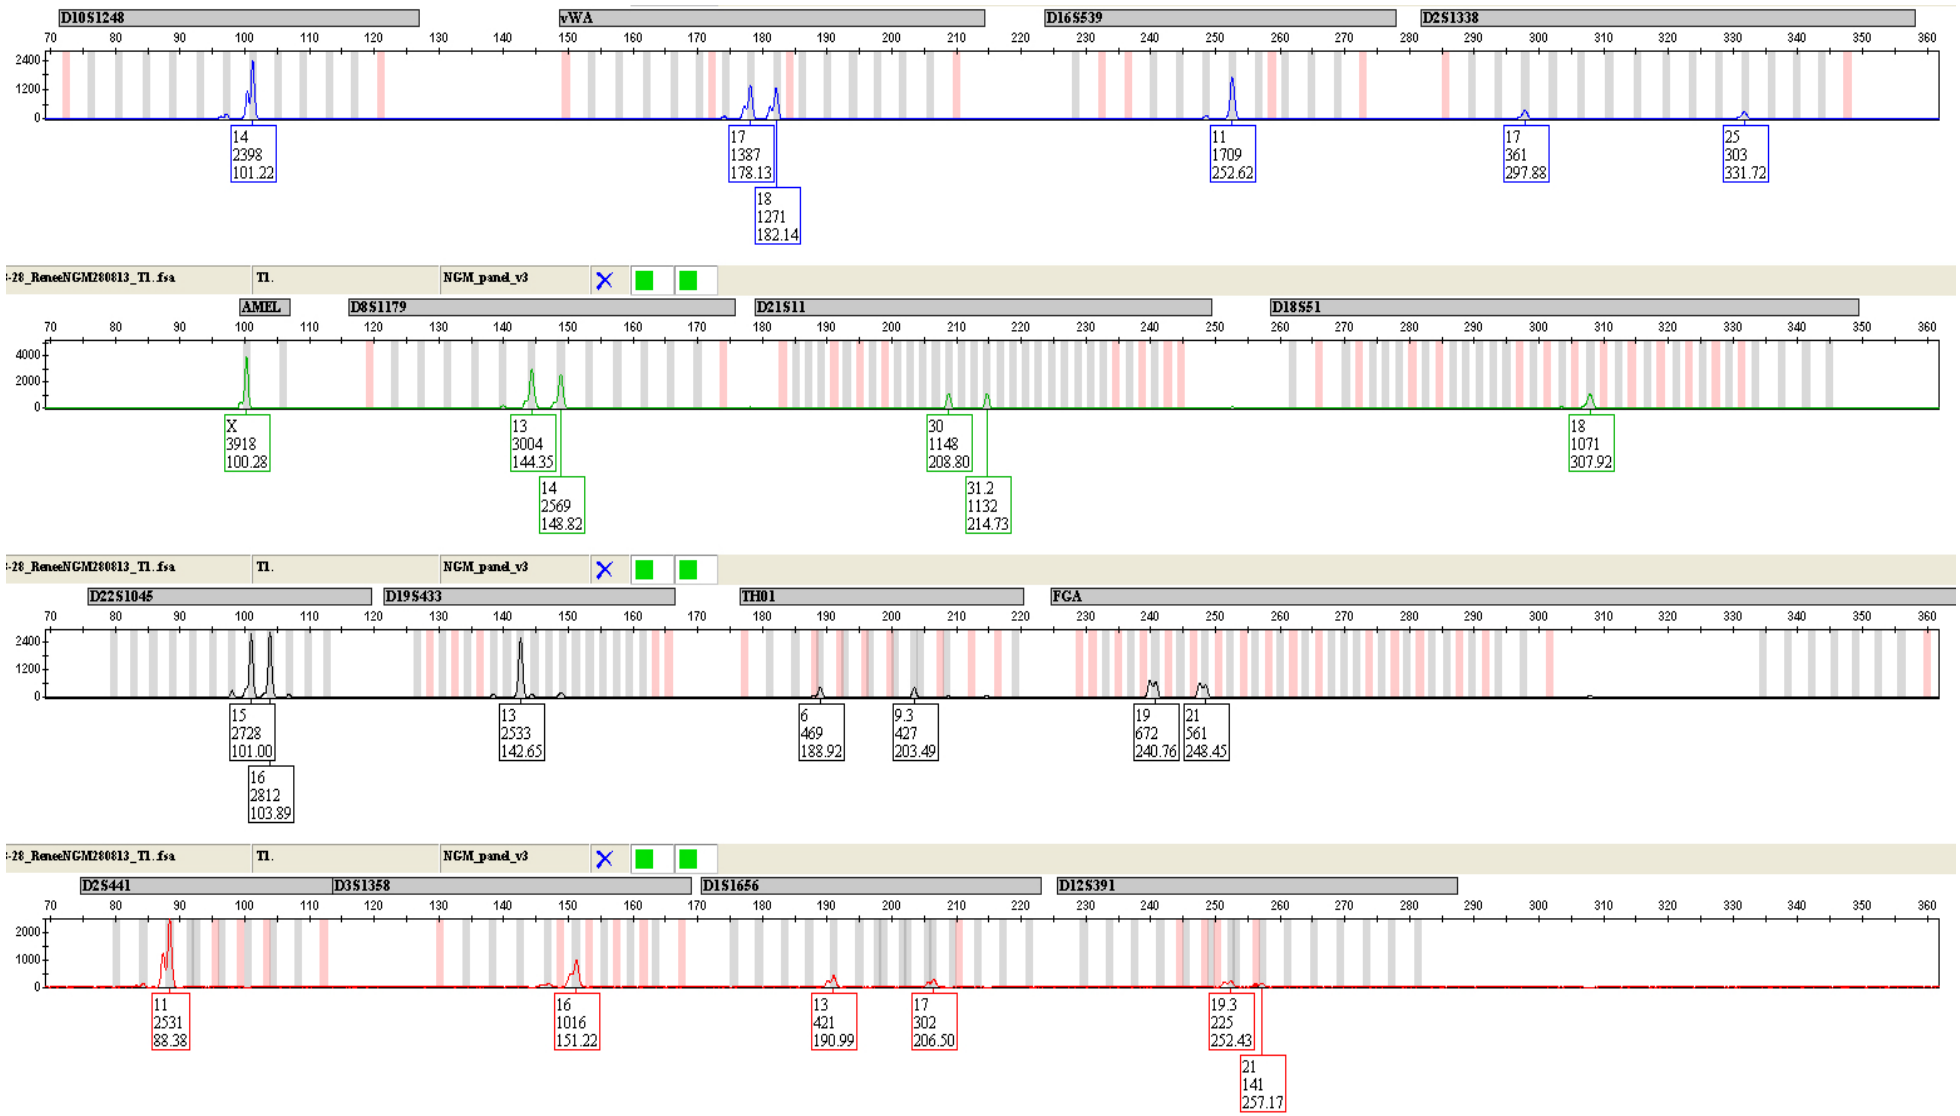

Figure 8.2 – Chromatogram of nuclear DNA from tooth powder amplified directly using AmpFℓSTR® NGM™ kit at 29 cycles on a GeneAmp® System 9600 thermal cycler. Sample was injected on an Applied Biosystems 3130*xl* Genetic Analyser at 3 kV for 10 s.

8.2.2 Flinders DNA Laboratory projects

Early on into this candidature, it was clear that the spectrum of substrates to research using direct PCR was too large to properly investigate in one research project. The second direct PCR candidature, undertaken by Jennifer Templeton, focuses on the use of swabs with touch DNA. Swab fibres are amplified directly after swabbing an area of interest. Unlike fibres from clothing and textiles, variables can be kept constant when using forensic swabs. Preliminary data showed nylon FLOQswabs™ to give the best DNA profile results when compared to various other swab types, such as cotton and foam. Using control DNA deposited onto brass, plastic and glass, swabbing with FLOQswabs™ and amplifying the swab fibres directly was shown to improve DNA recovery when compared to standard extraction processes [15]. Following the results of this experiment, a mock case study was developed to determine if DNA from fingermarks could be obtained from various substrates using direct PCR [16]. The method summary was published, reporting the generation of interpretable profiles from 71 % of 170 fingermarks [17]. The method is rapid, allowing for a reduction in associated costs, and eliminates the need to increase PCR cycle number. The technique also provides a new tool to obtain DNA from fingermarks, where previously fingermarks may have only been submitted for fingerprint analysis.

Fingermarks or touch DNA present at crime scenes can be challenging for collection as their location is mostly assumed, meaning DNA is not always present at the areas targeted for swabbing. The flow on effect is that many touch DNA samples submitted for analysis contain little or no DNA. The candidature undertaken by Alicia Haines investigates the *in situ* detection of latent DNA using DNA-binding dyes [18]. The fluorescence of the dyes where DNA is present can be observed easily using a Polilight®, allowing for a more targeted approach in the collection of touch DNA. With the right concentration of dye, ridge detail within a fingermark can also be observed allowing for fingermark comparisons to be made [19]. The dyes investigated have no significant effect on DNA extraction, amplification (direct or standard), and STR typing [20, 21]. Applying this technique to single hairs allows for rapid screening to determine if sufficient DNA is present for successful profiling [22, 23]. Combining this technique with direct PCR has further improved the DNA typing success rate of this difficult sample type [21].

The combination of techniques being developed in these three candidatures is creating powerful new tools for the rapid detection and targeting of trace DNA from difficult substrates with high DNA typing success rates. These techniques all adhere to current manufacturer protocol recommendations, without the increase of amplification cycle number, providing results fast and at a lower cost.

8.2.3 Explosive devices

Explosive devices used in terrorist attacks and bombings present a great challenge in investigations to identify the perpetrator, as the strong blasts often create incredibly small fragments of evidence [24]. Touch DNA is likely to be present on the components of explosive devices, transferred during assembly. The Omagh car bombing of 1998 (*Sean Hoey v. R*) was one of the first cases where LCN was implemented, generating a DNA profile from the wires associated with the bomb. Explosive devices are often made from household items, utilising electrical tapes and wires, batteries, and mobile phones, with containment in items such as PVC pipes, cookware, and backpacks [25-27]. The success rates for DNA STR typing of explosive device components are low [25, 27, 28], with the explosion itself likely to cause DNA degradation [25, 26]. Direct PCR has shown it can successfully amplify DNA from small fragments of fibres, keratin (hair and nails), and plastic (tape lifting), improving success rates in all cases. A recent study implemented direct PCR on simulated explosive device components, electrical tape and copper wire, as part of a larger study to determine the most efficient collection methods with explosive devices [29]. The sample size is low with only ten electrical tape samples, and ten copper wire samples amplified directly, yielding DNA recovery percentages of 20 – 35 %. The success rates are likely to increase if direct swabbing techniques [15], or a Triton™ X buffer soak (amplified directly) [16], are also implemented.

8.2.4 Wildlife crime

The illegal wildlife trade has a devastating and cascading effect on many animals, plants and their natural habitats. The UN estimates that 500 million shipping containers travel the world each year, and that less than 2 % are physically inspected [30]. Much of these containers are originating from under-developed countries and arriving at under-monitored ports, making it extremely difficult to determine the scale of illegal wildlife trade [31]; however, the wildlife forensic community estimates the trade at $20 billion per year [32, 33]. The discipline is greatly underfunded and is not prioritised in most forensic laboratories [33, 34].

Direct PCR is now becoming a popular tool to help combat illegal wildlife trade, as it is fast, cost effective, only requires a minute sample size, and is effective with trace DNA samples. Direct PCR of keratin substrates has been greatly successful throughout this candidature. Keratin substrates are also common in the animal kingdom, making up a large portion of illegal wildlife trade. Alpha keratins can be found in hair (wool), horns, nails and claws of mammals. Harder beta keratins are found in: the nails, scales and claws of reptiles; the shells of turtles and tortoises; the feathers, beaks and claws of birds; and the quills of porcupines, to name a few.

Mammalian samples of bone, ivory, horn, feces, urine, dried skin, 30-year old hair, muscle tissue, and antler have all successfully been amplified using direct PCR [35-37]. Direct PCR can also aid with species identification by enabling DNA to be obtained from the smallest of museum samples, samples that typically need to remain intact [38]. Traditional extraction methods would require too large of a sample in most cases, causing damage to the original item. Since the beginning of this candidature, other science disciplines have also begun to utilise direct PCR. DNA has been successfully amplified directly from leaf and stem tissues from fibre crops [39, 40], woody plants [41], and insect skins [42]. These substrates are all relevant to wildlife crime analysis.

Furthermore, animal SNP markers are becoming an increasing focus in the wildlife forensic field to help assist in species identification and the amplification of degraded DNA samples [34]. As previously shown, using direct SNP methods are successful on difficult keratin samples and would be another means of fast and cost effective identification within this field.

8.3 Final statement

The research contained within this thesis has undoubtedly highlighted the huge advantage direct PCR techniques has had within the forensic science community and beyond. The published data has facilitated new projects, not only within our own laboratory, but nationally and worldwide [15, 21, 34-45]. The stepping-stones for multidisciplinary collaboration have been paved, with the combination of techniques providing new and powerful methods for data collection and analysis. The ultimate goal of any forensic research is to improve methods so as to gain more valuable information during investigations. Not only has direct PCR enabled better DNA recovery for difficult substrates, the process is also faster and cheaper than current standard methodologies. As the technique does not require validated protocols to be adjusted, it can be introduced with ease, with many laboratories now implementing and researching direct PCR techniques for casework purposes [46-54].
