## Simulating Flight from an Insect's Perspective

## "Try not. Do. Or do not. There is no try."

_— Yoda, Star Wars: Episode V - The Empire Strikes Back

This would not have been possible without all of the support I have received.
I would like to thank in particular my supervisors, Associate Professor Karin Nordström and Doctor Sherry Randhawa.

I would also like to especially acknowledge the undying love, understanding, and forgiveness given to me by my family and friends.

My deepest gratitude goes to all who have helped me along this long and winding road.

## Simulating Flight from an Insect's Perspective

#### Abstract

The aim of this project was to develop a program that would take as input threedimensional position trajectories filmed as part of a previous experiment. These positions were isolated from recordings of interactions involving Eristalis tenax hoverflies, and various other insects and inanimate objects. The program would allow the user to select which of the participants in the interaction was to be the observer, and a simulation of the original flight would be reconstructed from the perspective of that observer.

In order to perform this simulation, additional information not present in the original data had to be estimated. To test the validity of the methods used to create this simulation, the program also determined which interactions were likely to be pursuits, and which were not. This was achieved by using the characteristics of the simulation and the trajectories.

Although the methods were found to be consistent according to statistical tests, the determination of pursuit was inconclusive.

## List of Abbreviations

| Conspecific | Another animal of the same species. |
| :--- | :--- |
| CSV | Comma-separated value; a spreadsheet file format. |
| DOM | Direction of motion. |
| (d)TSDN | (Dipteran) target-selective descending neuron. |
| Heading | Direction in which the head is facing. |
| Hoverfly/hoverflies | Eristalis tenax hoverfly/hoverflies, unless specified otherwise. |
| LED | Light-emitting diode. |
| LOS | Line of sight; the direct line between the two participants. |
| NaN | Not a number. |
| (3D) Pose | The combination of (3D) position and orientation. |
| STMD | Small target motion detector. |

## 1. Introduction

The aim of this project was to develop a piece of code that would integrate with FlyFly, the program currently used in the Motion Vision Lab (Henriksson 2010a). FlyFly was developed in 2010 as an alternative to the open-source visual stimuli program VisionEgg (Straw 2008), and was intended to better suit the specific requirements of the lab and its experiments. FlyFly is still used in the lab to display visual stimuli to Eristalis tenax hoverflies, referred to from here on simply as 'hoverflies', when conducting electrophysiological experiments.

This project aimed to allow for the expansion of earlier work done by Thyselius et al. (2018), who recorded interactions that occurred when investigating hoverflies being approached by other insects while feeding in the field. The hoverflies featured in these recordings interacted with either other hoverflies, wasps, bees, or inanimate beads. Hence, not all recorded interactions are between two insects of the same species.

From these interactions, the three-dimensional positions of both of the participants involved were tracked using a high-speed stereo videography setup. The process by which this was achieved will be further elaborated in 1.1. Background and 2.1. Tracking Insect Flight.

The code developed as a result of this project would take datasets such as those obtained by Thyselius et al. (2018) as input. The code would then utilise the existing FlyFly assets to simulate flight from the perspective of one of the participants involved. The user would have the ability to select which participant would provide its perspective as the basis of the flight simulation.

To validate the performance of this code, in light of challenges that will be elaborated in 1.1. Background, 2.3. Characterising and Modelling Flight, 2.4, Trajectory Reconstruction and Flight Simulation, and 2.7. Heading Estimation and Machine Learning, the code aimed to further be able to determine which interactions are and are not pursuits.

### 1.1. Background

Hoverflies are prime candidates for study in the areas of both neuroscience and aeronautics, due to their relatively simple brain consisting of only one million neurons, as well as their ability to perform fast and agile flight manoeuvres both in constrained environments and in free flight (Geurten et al. 2010; Thyselius et al. 2018). Hoverflies have been studied in flight since the 1970s but this early work focussed on the aerodynamics and mechanics of their flight, rather than the behaviour (Golding, Ennos \& Edmunds 2001).

In this research, conventional stimuli presented to hoverflies is usually unnatural, often consisting of rotating stripes or expanding circles. Ideally, naturalistic conditions must be provided to an animal in order to observe truly naturalistic behaviour (Geurten, Kern \& Egelhaaf 2012; van Hateren et al. 2005). When using algorithms based on un-naturalistic stimuli to predict responses to naturalistic stimuli, the algorithms may fail (Dyakova \& Nordström 2017).

In addition to unnatural stimuli, experimentation is usually performed on hoverflies that are tethered - fixed in position using wax - in open-loop paradigms (Fry et al. 2008). Openloop paradigms experimentally decouple the sensory stimulus from the motor behaviour, presenting visual stimuli and recording motor responses without altering the stimuli despite the animal's attempts to move (Fry et al. 2008; 2009). As a result, the feedback loop involving the visual system and the motor output normally present in free movement is broken (Fry et al. 2008).

The transferability of results from experiments using these open-loop paradigms to natural free flight is therefore unknown due to the experimental constraints (Fry et al. 2008; 2009). Additionally, the possible stimuli that can be presented to insects in such open-loop paradigms is limited in intricacy (Bagheri et al. 2014b).

This project aims to create a naturalistic stimulus for use in hoverfly research, by simulating flight from the perspective of a hoverfly using the three-dimensional position data taken from real interactions between two insects in the field.

The recordings were taken using cameras with high temporal resolution - a capture frequency of 120 Hz , recording every 8.33 ms - but a relatively low spatial resolution of $640 \times 480$ pixels (Thyselius et al. 2018). As a result of the low spatial resolution, the participants in the interactions are often difficult to distinguish. This is amplified by the high level of visual clutter, i.e. the background has similar colours and textures to the insects that are to be tracked (Acosta 2010). As a result, tracking the participants often necessitated manual input, as there was insufficient contrast between the participants and the background, even when measures were taken to improve contrast (Thyselius et al. 2018).

Figure 1.1 shows scenes from two separate recordings, illustrating the vast difference in visibility of insects across the recordings.

Figure 1.1: Demonstrating the variation in visibility of insects in the recorded interactions (Thyselius et al. 2018). Left: one participant is clearly visible against a flower in the upper centre of the image. Right: neither participant is clearly visible.

The participants in these interactions always involved at least one hoverfly of the species Eristalis tenax, found all over the world, often called drone flies due to their visual similarity to honeybee drones (Golding, Ennos \& Edmunds 2001; Thyselius et al. 2018). The term hoverfly will be used in this thesis to refer to Eristalis tenax, despite their additional name.

## 1. Introduction

In the literature, the term hoverfly is often used to refer to a wide range of dipteran insects, such as Syritta pipiens and Episyrphus balteatus. For this reason, care must be taken to differentiate between these different species of flies when referred to as hoverflies. Hence, the use of the term hoverfly in this thesis refers exclusively to Eristalis tenax, with other species referred to unambiguously.

Figure 1.2 shows an Eristalis tenax hoverfly alongside an Apis mellifera honeybee, illustrating how the unarmed hoverfly and the honeybee with its stinger are almost visually identical. For illustration, other insects commonly called hoverflies are also shown.

The outcome of this project will be a program that will take three-dimensional position data as input, representing flight sequences, and simulate this flight from the perspective of either insect participant as a stimulus for use in further electrophysiological research.

However, due to the limitations of the original experimental setup, this position data does not include any information on the direction of flight of the insects involved. This is problematic as the accurate reconstruction of a flight from the perspective of the original pilot relies on the way it was facing throughout the flight, as this has a direct effect on the information seen by the flying animal over the course of the flight.

The information seen by an animal as it moves through space is termed optic flow. Optic flow is rigorously defined as "the change of structured patterns of light on the retina that lend to an impression of movement of the visual imagery projected onto the retina," and gives animals the ability to visually estimate their own motion (Raudies 2013). When an animal moves, its optic flow is composed of the perceived relative motion of the animal's static surroundings generated by the animal's own motion, in addition to the real motion of other moving objects (Boeddeker et al. 2005).

## 1. Introduction

Figure 1.3 illustrates this concept by recolouring different components of the field of vision according to how they would be perceived by an animal in motion. Each of the coloured components in Figure 1.3 would appear to be moving, due to the viewer's self-motion.

Image removed due to copyright restriction.

Figure 1.3: An illustration of optic flow (Gonzalez-Bellido, Fabian \& Nordström 2016).
In Figure 1.3, the viewer is moving straight forwards, hence the optic flow radiates from the centre of the image. The backboard and net are static figures, but would appear to move as a result of the viewer's own motion. In this case, the viewer would perceive the backboard and net to be moving nearer to them and also vertically higher, as indicated by the lines in Figure 1.3. The other players - dynamic figures - would also be perceived by the viewer to move, according to how they are indeed moving in the real world.

The optic flow illustrated in Figure 1.3 is conceptually simple, as the direction of motion is aligned with the direction in which the viewer is looking. However, the optic flow observed by an animal in motion depends not only on the direction it is moving, but also on the direction it is looking, from here on termed 'heading'. Figure 1.4 illustrates the effect a change in heading has on optic flow.

Image removed due to copyright restriction.

Figure 1.4: Different heading with same direction of motion produces different optic flow. Left: going forwards, and Right: going backwards along the same track (Ellis 2014).

In Figure 1.4, the rollercoaster traverses the same track in both instances, but facing in different directions. The arrows indicate the perceived motion of those elements of the visual field. As a result, although both images feature the same direction of motion, indeed along the same path, the difference in heading produces different optic flow.

Similarly, a heading far from the true heading for the simulated hoverfly flight would produce totally different optic flow to that which would have been experienced by the hoverflies in the recordings. In order for the simulated flight to be realistic, the optic flow presented to the viewer must realistically represent that which would have been experienced by the original flying insect.

This is one major challenge of this project, as the data supplied as the basis of this project lacks information on the orientation of the body and head of the insects. In order to correctly represent the optic flow, the heading of the insects at each frame must therefore be estimated. This estimation will form the bulk of the project, and the accuracy of the simulation will depend on the factors used in this process of estimation.

As the orientation of the body is not considered in this project, the (unrealistic) assumption that the head and body are aligned (Land 1992; Olberg, Worthington \& Venator 2000) does not need to be made.

### 1.2. Relevant Technologies

Similar technologies to FlyFly already exist, with different solutions being found to the problem of creating naturalistic stimuli. FlyFly itself was created in an effort to improve upon the VisionEgg software (Henriksson 2010a). However, using trajectories from recorded flights in the wild is a different question. As will be outlined in 2.4. Trajectory Reconstruction and Flight Simulation, other studies have attempted to display reconstructed flights to insects, however, these had other limitations.

One technology of note is GapFlyt, an autonomous flying vehicle which makes use of optical flow and parallax to detect holes. By taking pictures around a hole, and analysing which features appear to have moved more or less than others between pictures, the edges of a hole can be approximated (Ackerman 2018). In this way, visual information from the cameras provides closed-loop feedback to the motors, altering flight in real time. However, GapFlyt relies on textured features, and would not perform as well on walls painted white (Ackerman 2018).

### 1.3. Research Objective

As laid out in 1.1. Background, this project aimed to create a program that would simulate hoverfly flights given 3D data tracked from interactions recorded in the field. This simulation would run using the FlyFly visual stimulus program currently used in the Motion Vision Lab.

The performance and hence validity of the created program would be evaluated by using the simulations to determine which interactions were and were not pursuits, based on the characteristics of the simulation.

## 1. Introduction

By reconstructing interactions which may have been pursuits, target detection can be evaluated alongside optic flow. Depending on the direction of motion, optic flow may help or hinder target detection (Nicholas et al. 2018), and so this project will have a direct future application in research, with its resultant visual stimuli being planned to be used in electrophysiology.

As a whole, small target detection, particularly in visual clutter, has applications in fields such as automation and defence, particularly in bio-inspired robotics.

## 2. Literature Review

A literature review was conducted using the Google Scholar, ScienceDirect, PubMed, and IEEE Xplore databases to search for articles investigating tracking insect flight in three dimensions, modelling insect flight for the purposes of biomimicry, and otherwise characterising insect flight behaviours. The review also searched for articles regarding simulating flight, reconstructing trajectories from discrete points, estimation of heading, displaying optic flow, insects' ability to detect targets in background clutter, and general hoverfly behaviour.

As a result, this literature review has been divided into seven sections, according to the order in which the project considered these areas. First, the tracking of flight in three dimensions was investigated, in particular comparing different experimental setups. Next, hoverfly behaviour was explored, in an effort to find elements that could be used in determining a strategy for flight control. Third, this was expanded upon in flight characterisation and modelling. In the fourth section, reconstruction of trajectories was investigated, in order to consider alternative methods to flight simulation. Fifth, display of optic flow was investigated, considering different methods of doing so. The sixth section looks at insects detecting targets in cluttered backgrounds, again to look for elements to include in a flight control strategy. Finally, the main focus of this project, heading estimation, was considered. Machine learning was also investigated.

### 2.1. Tracking Insect Flight

To obtain the data to be used as input in this project, two cameras were set up orthogonally, allowing the centre of mass of each insect to be mapped in three dimensions (Thyselius et al. 2018). For each two-insect interaction, the positions of the insects were recorded as a set of XYZ-coordinates, isolated at each frame. This experimental setup was very similar to that used in other studies, and in particular followed previous work done by Wardill et al. (2017).

However, unlike other studies, the experimental setup from whence the data was obtained could not enable the orientation of the insects' bodies nor their heads to be determined (Geurten et al. 2010; Geurten, Kern \& Egelhaaf 2012; Golding, Ennos \& Edmunds 2001; van Hateren et al. 2005). This was due to the low resolution of the footage obtained and the highly textured surroundings, meaning at times the hoverflies were unable to be identified by the image processing software (Thyselius et al. 2018).

Olberg, Venator, and Worthington (2000) simplified measuring body orientation by characterising interactions in a plane perpendicular to the axis of the camera lens, allowing angles to be used to describe the orientation of the insects' bodies. However, this could only be done when the insects flew roughly at right angles to the camera.

Other studies overcame this problem in different ways. In order to be able to identify body orientation during flight, Geurten et al. (2010) utilised an experimental setup in which one camera filmed hoverflies from above, in addition to another camera filming from the side. Similarly, Boeddeker, Kern \& Egelhaaf (2002) used one camera recording from the side and
another from the bottom, orthogonally oriented, to capture body orientation. Although not in insects, Eckmeier et al. (2008) used a one camera above, one camera from the side setup to record the movements of finches in three dimensions. In each of these experiments, aligning the two cameras orthogonally, as opposed to a simple angular offset, was necessary to identify the orientation of the animals' bodies in 3D space, not simply position.

In those studies, however, this was made possible by the animals being observed within cages of various sizes, constraining the area in which they were able to fly, unlike the data provided which was recorded outdoors. Alternatively, some setups made use of a uniform background, in order to improve contrast. Additionally, the method used in the experiment done by Thyselius et al. (2018) was deliberately chosen to be easy to set up and calibrate, in order to be able to be used in a wide range of settings. As this data was gathered in the wild, as opposed to within a constrained area, the interactions should therefore more closely resemble truly naturalistic behaviour, and thus when used as stimuli should be more naturalistic, in turn evoking a more naturalistic response.

As outlined in 1.1. Background, the orientation of an animal's head is involved in controlling its gaze, and as a result affects its perceived optic flow (Boeddeker et al. 2005; Eckmeier et al. 2008; Geurten, Kern \& Egelhaaf 2012; van Hateren et al. 2005; Lindemann et al. 2003; Tammero \& Dickinson 2002). If the orientation of the head cannot be tracked in flight, the body orientation can be used to approximate the orientation of the head instead (Boeddeker et al. 2005; Tammero \& Dickinson 2002). To overcome the limitation of having no information on head orientation, it was assumed that the insects faced straight ahead in the direction of flight, with the concession that this assumption would likely not hold outdoors, and that the reconstructed optic flow would not be completely true to life (Boeddeker et al. 2005; Tammero \& Dickinson 2002). This assumption was based on the fact that both Calliphora vicina blowflies and Drosophila melanogaster fruit flies face in the direction of flight for the majority of cruising flight.

In the other aforementioned experiments, the resolution of the images obtained from the orthogonally oriented cameras was high enough to determine the orientation of the head in addition to the body (Geurten et al. 2010; Geurten, Kern \& Egelhaaf 2012; Golding, Ennos \& Edmunds 2001). Instead of using a camera to track the head position of blowflies, van Hateren et al. (2005) used a slightly different approach, measuring voltages induced by magnetic coils embedded in the blowflies' heads to track their positions relative to the cage in which they were filmed flying. As a result, trajectories could be established for not just the body but also the head, subsequently describing exactly the path taken by the animal, and its heading along that path. Goulard et al. (2015) also achieved this, using a high-resolution camera and a uniform background to track natural markers on the head of the insect and thereby determine its orientation.

In order to demonstrate that naturalistic stimuli could be created from trajectories lacking information on head orientation, van Hateren et al. (2005) reconstructed a set of trajectories with head orientations and one without. The article referenced Collett and Land's landmark 1978 paper on hoverflies, which did not record in three dimensions,
determining only body position and rotation in the pitch axis. Similarly, although Golding, Ennos, and Edmunds (2001) used a camera from above, body positions were recorded in only two dimensions, allowing for the construction of flight paths but with no information on altitude or body orientation. Van Hateren et al. (2005) noted that naturalistic stimuli could be created from trajectories like these, but that any flight that included sequences of sideward translation would lead to the generation of sideward optic flow. Hence, operating on the assumption that the direction of gaze does not differ from the direction of body orientation would lead to an unrealistic flight trajectory, and in turn an inaccurate flight simulation.

Although it is fallacious to assume that the head position of an insect can be used to infer its body position (Olberg, Worthington \& Venator 2000), with some smaller insects, head orientation is tightly coupled to body orientation (Land 1992). However, in this project the head position will be estimated independently of the body position, thus making no assumptions about the coupling of body orientation to head position.

### 2.2. Hoverfly Behaviour

Pursuing prey is not the only motivation for insect pursuit flights; both dragonflies and hoverflies pursue members of their own species, termed 'conspecifics' (Land 1992). Pursuit of conspecifics usually entails males chasing females in order to mate. When pursuing females, male hoverflies use an interception strategy, aiming ahead of the female (Olberg, Worthington \& Venator 2000). In interception, the image of the prey on the pursuer's retina is held at a constant angle offset from straight ahead, which has the effect of minimising the drift of the retinal image of the prey (Olberg, Worthington \& Venator 2000).

When in pursuit, male hoverflies and dragonflies pursue targets from below and behind, fixating their targets in the dorso-frontal visual field (Nordström \& O'Carroll 2009). By doing so, the target can generally be visualised against the open sky, improving contrast. This behaviour correlates with the fact that male hoverflies have a region in their field of view wherein light capture is increased, termed the "acute zone" or the "bright zone" (Nordström \& O'Carroll 2009; Straw, Warrant \& O'Carroll 2006). This adaption possibly improves contrast of targets in this region, and male hoverflies keep females fixated in this zone when in pursuit (Straw, Warrant \& O'Carroll 2006).

Hence, trajectories that result from male hoverflies chasing females would be expected to show the target being kept in the upper-frontal part of the display.

### 2.3. Characterising and Modelling Flight

In order to characterise and model the complex flight behaviour of hoverflies, numerous studies have attempted to break it down into simpler pieces. The same approach has been taken in describing other types of complex motion, such as defining the movements of mice in terms of simple sequences that occur often, recognising movements that make up sign language, as well as in building locomotion from small movements (Braun, Geurten \& Egelhaaf 2010; Geurten et al. 2010).

## 2. Literature Review

The flight of many species of flies, as well as that of birds and bees, has been shown to consist of short fast turns, called saccades, and segments of non-turning flight in between (Boeddeker et al. 2005; Eckmeier et al. 2008; Geurten et al. 2010; Geurten, Kern \& Egelhaaf 2012; van Hateren et al. 2005; Tammero \& Dickinson 2002). Geurten et al. (2010) further classified the flight of hoverflies into nine 'prototypical movements,' which form basic building blocks to describe flight sequences. Braun, Geurten, and Egelhaaf (2010) also were able to classify blowfly flight into nine prototypical movements.

As outlined previously, the heading of the insects will have to be estimated in order to provide an accurate simulation of the original flight. With the paths of motion provided in the three-dimensional position data, the prototypical movements and the transition probabilities between these prototypical movements can be used to better inform the estimated heading throughout the flights. Figure 2.1 shows the prototypical movements determined for hoverflies.

## Images removed due to copyright restriction.

Figure 2.1: Prototypical movements determined for a hoverfly (Geurten et al. 2010). Left: a diagrammatic representation of the colour-coded prototypical movements. Right: a schematic explanation of the terms of reference for the colour coding.

Geurten et al. (2010) found their hoverfly prototypical movements applied largely equivalently in two different sizes of flight arenas. Boeddeker et al. (2005) also found that blowflies exhibited the same flight styles whether confined in a cage or observed in the wild. Geurten, Kern, and Egelhaaf (2012) compared the data from Geurten et al. (2010) and Braun, Geurten, and Egelhaaf (2010), concluding that hoverflies and blowflies both separated flight into saccades and straight flight, and that the optic flow during saccades was similar for both species. Despite this, the optic flow in straight flight was very different between the two species. As a result, blowfly movement sequences cannot be used to characterise the flight of hoverflies, but those of hoverflies can.

Although these prototypical movements were initially promising for this project, they rely on knowledge of the heading of the insect. Instead of assigning a prototypical movement
to a section of flight based on its heading, it is perhaps possible to instead use a distribution of prototypical movements over the entire flight. The heading could then be determined to match that section of flight to the prototypical movement, but this will have to be explored in further work.

### 2.4. Trajectory Reconstruction and Flight Simulation

The stimuli displayed to insects under study classically has consisted of either moving stripes or moving dots. Prior to the advent of these stimuli being generated electronically, these stimuli were the only stimuli able to be generated mechanically. The aim of this project is to produce a stimulus that will be more naturalistic than these simple illusions of motion.

Displaying a reconstruction of flight to hoverflies as a stimulus has been attempted before (Boeddeker et al. 2005; Geurten, Kern \& Egelhaaf 2012; van Hateren et al. 2005; Lindemann et al. 2003; 2008; Tammero \& Dickinson 2002). However, with the exception of Boeddeker et al. (2005), the insects from which these simulations were reconstructed were filmed flying in cages. As a result, the reconstructed flights could only show the interiors of the cages in which they were filmed. Boeddeker et al. (2005) were able to film blowflies outside, but due to the physical limitations of the camera setup, the video could only be replayed at 1 frame per second. This is well under the temporal resolution of fly vision, and had the effect of over-exaggerating the motion of the background surroundings. Thyselius et al. (2018) recorded hoverflies outside at 120 frames per second, and so this problem would not be present in the data provided. However, it must be noted that for different experimental setups, different display frequencies may be used for stimuli, and so the final product must be able to be resampled to match the display.

As has been outlined previously, in order to simulate flight, the original trajectory and heading must be established from the data provided, which consists in this case only of points in three-dimensional space. This is certainly possible, as shown by O'Neill (2000), who used only the position and acceleration data from a flight recorder to accurately drive a helicopter flight simulator.

In order to create a realistic simulation, a realistic path must be constructed between the positional points. Al-Jarrah and Hasan (2009) investigated a method for an unmanned aerial vehicle to plan a flight path between 3D waypoints in real time, making reference to Dijkstra's algorithm. This algorithm is used to find the shortest path between points, and may be useful in establishing a baseline path that can be adjusted according to the movements realistically available to the hoverflies to create a path through the points.

For direct applicability to hoverfly flight, the prototypical movements mentioned in 2.3. Characterising and Modelling Flight, found by Geurten et al. (2010), would be the main basis for adjusting the path flown by the hoverflies. Geurten et al. (2010) established a Markov model for the hoverfly movement sequences, which is a set of discrete states and the probabilities of transition between those states (Wallisch et al. 2014). By creating a Markov model, it is then possible to apply the Viterbi algorithm, used to determine the
most probable path through the Markov states taken to generate a set of observed outputs (Wallisch et al. 2014).

Both Markov models and the Viterbi algorithm are straightforward to implement in MATLAB, but simple Markov models may not describe the system fully. Hidden Markov models are extensions of simple Markov models that describe the probability of each state not only transitioning between states, but also of outputting multiple possible outputs, and are able to model systems more comprehensively (Wallisch et al. 2014). These hidden Markov models can then be refined using the Baum-Welch algorithm to determine each state's probability of output. In this way, the Markov model provides a method to not only describe the reconstructed flight sequences but also measure their accuracy.

For this project, the observed outputs would be the three-dimensional positions recorded by Thyselius et al. (2018). A Markov model could be constructed using the states and the transition probabilities from Geurten et al. (2010). The Viterbi algorithm and the BaumWelch algorithm would then be applied to estimate the most probable path taken by the hoverfly to pass through those points, also giving an estimation of the heading between the points. This information could then be used to construct a simulation.

Geurten et al. (2010) made a comparison between the prototypical movements and transition probabilities to words and the grammar connecting those words in natural language. In this project, the data provided gives only the words, and the grammar from established literature will have to be applied in order to make meaningful sense of the story.

### 2.5. Display of Optic Flow

If the simulations are to be displayed in real-time, as captured by Thyselius et al. (2018), they will appear very fast to the human eye. For comparison, dragonfly pursuit flights were found to have an average duration of 184 ms , calculated from the point where pursuit was commenced to capture (Bagheri et al. 2015). The simulations from this project can be expected to last only a few seconds, and display motion at a very fast rate.

Reproducing naturalistic visual stimuli in an experimental setting is complicated, as existing visual displays are limited in terms of the naturalness of the stimuli they can be used to display (Dyakova \& Nordström 2017). In order to evaluate insect vision in the natural world, the natural world must first be able to be displayed. LED arenas, commonly used to display optic flow, have sufficient temporal resolution, however, their spatial resolution is generally too low for the optical resolution of hoverflies (Dyakova \& Nordström 2017). The spatial resolution of LED arenas depends on the size of the LEDs used in construction, which generally ranges between 2 and 4 degrees in diameter (Henriksson 2010a). Hoverfly eyes have a spatial resolution of 1 to 2 degrees, which can be approximated as the width of a thumb at arm's length (Henriksson 2010a; Nordström, Bolzon \& O'Carroll 2011).

The temporal resolution of hoverfly vision is more than double that of a human's, at about 125 Hz compared to around 50 (Henriksson 2010a). Temporal resolution can become an issue when the motion between two successive images in an animation is too large,
thereby appearing jerky (Henriksson 2010a). One way to combat this is to use motion blur between the two positions, effectively smoothing the motion by reducing the change between frames (Henriksson 2010a). This feature is not implemented in FlyFly at present.

Bagheri et al. (2014b) used a cylindrical arena to display simulated motion of a target against a static background. The insect was able to pursue the target within the arena, with the target being manipulated to not collide with the walls of the arena. The target was also manipulated such that it would not be lost from view each time it turned (Bagheri et al. 2015). This would artificially force the target to remain in the field of view at all times. Not only was the target's position maintained within the viewport of the camera, rotations were also performed in order to keep the target fixated no more than 5 degrees from the centre of the frontal field of view (Bagheri et al. 2015). As a result, the target was always near the centre of vision.

### 2.6. Target Detection in Visual Clutter

Dipteran target-selective descending neurons (dTSDNs) are unresponsive to targets moving in visual clutter, unless the background meets certain requirements (Nicholas et al. 2018). Diptera is the order to which hoverflies, blowflies, and fruit flies - among other flies - belong. Naturalistic backgrounds suppress the responses of dTSDNs, and hence dTSDNs are responsive to backgrounds with un-naturalistic spatial characteristics (Nicholas et al. 2018). Additionally, if the background is perceived to be moving slowly or in the opposite direction relative to the target motion, dTSDNs will respond.

It is suggested that the unresponsiveness of dTSDNs to target motion in the same direction as that perceived to be of the background is due to the rarity of this occurring in actual target pursuits (Nicholas et al. 2018). For target motion and perceived background motion to be in the same direction, the observer must be turning away from the target, causing the background to appear to move in the opposite direction.

By hovering, the perceived background motion due to self-motion is minimised, maximising the dTSDN response, and so hoverflies often detect their targets whilst in a hovering flight pattern (Nicholas et al. 2018; Nordström \& O'Carroll 2009).

In addition to TSDNs, small target motion detector (STMD) neurons have been described in hoverflies, which exhibit strong responses to the motion of small targets against backgrounds with visual clutter (Nordström, Bolzon \& O'Carroll 2011). These STMDs exhibit an ability to track targets moving in non-continuous paths until the interruption is higher than a threshold of approximately 7 degrees (Nordström, Bolzon \& O'Carroll 2011).

Additionally, neuronal response was found to build up as targets moved along continuous trajectories (Bagheri et al. 2015). In contrast to TSDNs, some STMDs respond to targets even when they move without a velocity relative to the background (Nordström \& O'Carroll 2009). Pursuits that failed to end in capture were found to be generally due to inadequate target detection rather than unsuccessful pursuit (Bagheri et al. 2014a).

If a hoverfly were able to perfectly follow the motion of its target, keeping the image of the target perfectly in the centre of view, the target would not be perceived to move at all
(Nicholas et al. 2018). Instead, the background would continue to be perceived to move. In order to investigate this hypothesis, reconstructed target pursuits can be replayed.

### 2.7. Heading Estimation and Machine Learning

In order to determine the heading of the hoverflies, their 3D orientation (in addition to their position) can be estimated. This combination of 3D orientation and position is referred to as pose, and pose estimation is a widespread challenge for computer vision. Pose estimation is used in automated industrial picking, human feature detection, and autonomous vehicle egomotion estimation, visually informing the vehicle of its own motion.

For ground vehicles, egomotion estimation techniques make use of the limited degrees of freedom to specify three-dimensional movement as a combination of forward translation and side-to-side yaw (Angelopoulou \& Bouganis 2014). This is insufficient for aerial motion, where translations and rotations alike can be performed in three dimensions, with six degrees of freedom. When using optic flow to determine self-motion, avoiding rotational motion can simplify the estimation of linear velocity from translational motion (Raudies 2013). Hence, heading becomes the direction of linear velocity, disregarding rotational motion (Raudies 2013).

Estimating 3D pose from a single image is inherently an under-constrained problem, as many 3D poses can project to the same image (Arnab, Doersch \& Zisserman 2019). Similarly, the same object projects different silhouettes according to its pose (Liu et al. 2012). With the data provided, the ground truth of the pose of the insects was not available, even given the video footage. Liu et al. (2012) circumvented the absence of ground truth by comparing the pose estimated from all eight cameras used with poses estimated from differing numbers of cameras, hence estimating the ground truth itself.

With a 3D model of a textured object, feature points can be matched between the model and images to estimate the pose of the object in the image (Mitash, Boularias \& Bekris 2019). However, this requires good lighting conditions and a 3D model of the object. When pose estimation is performed for industrial parts, 3D CAD models are usually readily available, and when not already existing, the number of identical parts processed lends to easy and accurate model acquisition (Liu et al. 2012). In this case, 3D models are neither already existing nor readily available for Eristalis tenax hoverflies, let alone the other species of insects that were participants in the filmed interactions.

In the field of human pose estimation, most existing datasets were collected in constrained lab environments, with uniform lighting, background, and viewpoints (Yang et al. 2018). In the context of this project, none of these characteristics are exhibited by the data. The data is instead typical of "in the wild" footage, with features such as occlusion, poor lighting, and motion blur (Arnab, Doersch \& Zisserman 2019). Most pose estimation algorithms, particularly those trained on uniform datasets, fail to estimate pose in the wild (Arnab, Doersch \& Zisserman 2019).

## 2. Literature Review

An alternative method to quantitative 3D pose estimation is ordinal depth assignment. By specifying which of two key points on an object is in front of the other, the relative depth ordering of each of the key points selected for an object can be assigned (Arnab, Doersch \& Zisserman 2019). In this way, a 3D pose for the object can be estimated.

Access to a large training dataset helps to both speed up an algorithm's learning, as well as improve its applicability to testing data (Liu et al. 2012; Ukita \& Uematsu 2019). When a large dataset is used, however, this data must be labelled, which requires a significant amount of manual effort (Kawana et al. 2018; Mitash, Boularias \& Bekris 2019). An alternative is to use synthetic data, however, there is an inherent difference between the theoretical examples synthesised as training examples and real-world testing data (Mitash, Boularias \& Bekris 2019).

## 3. Application and Implementation

### 3.1. Project Management

Originally, this project was planned for completion in May 2019. However, due to the limitations of the project, in particular those of the data, there were many challenges.

Initially, all of the elements described in the literature review were to be included, such as using prototypical movements and transition probabilities to validate heading estimations by measuring distributions of prototypical movements. However, the prototypical movements could not be determined without assigning a local coordinate axis to the fly, which in turn required an estimate of the heading.

Machine learning was also considered, in particular the use of computer vision. This was in fact attempted, with considerable time spent trying to label at least the orientation of visible hoverflies in the video footage. Ultimately this did not produce fruitful results.

Path planning, using flight dynamics in combination with behavioural studies, was also originally desired. Ideally, a flight strategy was to be developed, determining the heading most likely used to traverse between two successive data points.

These additional requirements led to scope bloat, pushing the endpoint of the project out to October 2019. Determination of pursuit was added at this point in order to simplify the project, removing these additional complicating features.

When reviewing the literature, there were even further methods that were found that could prove useful, but these must be explored in future work.

### 3.2. Aims and Specifications

The specifications for the end product of this project were quite straightforward. First, the program must accept the datasets provided by Thyselius et al. (2018) as input. The user must be able to select which of the two participants they wished to be the observer, and the other would thus be the target.

The output of the program would be a simulation of the recorded flight as would have been experienced by the insect itself. It was also specified that the program should be as straightforward to use as the existing software, and provide similar functionality, such as allowing for experimental variation.

One key specification was that the program must allow the user to adjust the output of the program, as they may have additional information or knowledge.

### 3.3. Deliverables and Requirements

The main deliverable of the project is the program itself, with the specified input, output and functionality as described above. It was established as a further requirement that data produced by the program should be saved for future use, and that the program should integrate with the FlyFly environment.

## 4. Methods

## 4. Methods

Initially, computer vision was investigated as an option for estimating the heading of the hoverflies. As the data consisted not only of the 3D trajectories but also the video recordings of the interactions, it was proposed that the videos could be used as a ground truth to be used to evaluate the accuracy of the heading estimation from the trajectories.

However, as illustrated in Figure 1.1, and outlined in 2.1. Tracking Flight and 2.7. Heading Estimation and Machine Learning, the resolution of the videos did not allow for the tracking of multiple points on the bodies of the insects. Indeed, even tracking the centre of mass of the insect was not a straightforward task, for both the computer and the user.

Johnson and Everingham (2010) were able to crop and scale labelled body parts in their experiments so that they were all roughly 180 pixels in length. In some parts of the videos for this project, however, the insects are indistinguishable from the background, and are only a few pixels in size. As a result, there was no way a point cloud could be registered to represent a model of the insect's body and thus determine its orientation.

The use of a visually uniform background facilitates object detection and tracking. The more different the colour of the background to the objects that are to be tracked, the less difficulty there will be differentiating between object and background (Acosta 2010). However, it is considered too restrictive for a general system to use a plain background, and algorithms trained on plain backgrounds will not be able to perform in natural situations (Acosta 2010). As the data used in this project was collected in the wild, the background present is naturally visually cluttered.

### 4.1. Data Validation and Pre-Processing

Firstly, the data had to be pre-processed to ensure it was valid. The original 16 datasets provided were uniformly in .mat format, with the 3D positions through the duration of the interaction given as a two-matrix cell. These matrices were of the same length, each having three rows. These rows specify the X -, Y -, and Z -coordinates, respectively, at each frame for each participant. Figure 4.1 shows part of a typical dataset.

Figure 4.1: The first few elements of a typical, valid, dataset. Above: matrix 1 of the twomatrix cell. Below: matrix 2 of the two-matrix cell.

At this stage, the dataset must be valid: it must be a two-matrix cell, with each matrix being the same size and having three rows. This is to ensure that there is XYZ data for both of the two participants over the entire interaction. For the purposes of this project, data that was deemed to be invalid was discarded. However, in future, the user should have the ability to edit invalid datasets. This could entail the program extrapolating from the present data in order to fill the gaps. As in 3.2. Aims and Specifications, the user must always retain control over how the data is adjusted.

A further 90 datasets were provided for analysis over the course of the project. When preparing the 106 datasets, 16 were found to be invalid. Datasets were given an ID according to the order in which they were taken from each individual folder of recordings. Each dataset is from a separate instance, however, some datasets come from different points in the same recording. Table 4.1 lists which datasets were invalid.

Table 4.1: Datasets found to be invalid during pre-processing. These invalid datasets are invalid as they do not consist of two matrices.

| ID of invalid dataset |
| :---: |
| 001 |
| 002 |
| 003 |
| 007 |
| 037 |
| 038 |
| 039 |
| 040 |
| 041 |
| 046 |
| 074 |
| 075 |
| 076 |
| 077 |
| 078 |
| 079 |

These datasets were unable to be used for the purposes of this experiment. Again, however, in future these datasets should be able to be edited and used in simulation. The validation code additionally relies on the imported dataset being of a specific format. For future use, this will have to be rectified in case datasets of different origin are used. If the datasets are deemed invalid, the program does not proceed.

### 4.2. Trajectory Reconstruction and Heading Estimation

After choosing the dataset to be processed, the user is able to specify which participant is to be used as the basis of the reconstruction. There are competing systems for how to term

## 4. Methods

the two participants - e.g. target and pursuer (Olberg, Worthington \& Venator 2000; Wardill et al. 2017), occupant and challenger (Thyselius et al. 2018), fly A and fly B. In the context of this program, observer and target are used. In this sense, the observer is the fly to whom the stimulus will be displayed. The target is the fly whose motion will be displayed relative to the observer's own position. The user selects this by specifying which matrix (1 or 2) represents the observer, with the other matrix representing the target.

It is also important to highlight the difference between motion and position. The datasets provide information on only the positions of the observer and target at discrete points in time. The direction of motion between those positions can only be inferred from the data points given. For this project, direction of motion was taken to be the straight line between position data points.

In a similar vein, the heading through the flight must also be inferred. The frequency at which the data points were captured is important to determining the direction of motion and heading, as well as to the accuracy of the simulation. The user is given the ability to specify this frequency, although Thyselius et al. (2018) claim the sampling frequency of the 3D position data to be $120 \mathrm{~s}^{-1}$. However, it should be noted that 120 Hz is below the upper temporal resolution limit of flies (Fry et al. 2008; Henriksson 2010a), and so ideally a higher capture frequency would be preferable.

The intention of this code is to provide an informed estimate of the heading of the observer, in order to accurately reconstruct the optic flow and the target motion. From there, the flight from the perspective of the observer can be simulated.

FlyFly uses gluPerspective in its 3D projection algorithm, which makes the assumption that the user is positioned directly in front of the screen, facing perpendicular to it, and looking directly at the centre of the screen (Kooima 2008). In more general terms, perspective projection requires the viewing point to lie on a coordinate axis intersecting with the view plane (Power 1996).

In its current state, the code aligns the observer's heading with either the observer's direction of motion ('DOM') between position coordinates, or the straight line (line of sight, 'LOS') between the observer and target at each position coordinate. In future, an algorithm will be added to the program that will use the trajectory to estimate the heading.

An ID was assigned to the resultant trajectory, depending on the method used to generate it. If matrix 1 was selected as the observer, obs 0 , representing a value of 0 for the observerFlag variable, used throughout the code, was appended to the ID. Similarly, if matrix 2 was selected as the observer, obs1 was appended to the ID. Then, if the direction of motion method was used to rotate the heading, dom was further appended to the ID. Otherwise, los for line of sight was appended. Hence, as an example, if matrix 1 in dataset number 043 were selected as the observer, and the line of sight method was used to rotate the heading, the resultant ID would be $0430 b s 0$ los.

By rotating the observer's estimated heading to the Z-axis, the coordinate axes for the simulation are also rotated such that the aforementioned perspective projection

## 4. Methods

requirements are met. 3D motion is then displayed as if a camera were attached to the observer through its flight, with forward motion displayed along the (negative) Z-axis. Figure 4.2 illustrates the process of rotating the coordinate axes in order to display flight from the perspective of the observer.

The fly has its own local coordinates depending on its heading. Take the Z -axis to represent the direction of its heading; let this be $\mathbf{f}$.

The local coordinates must be rotated to match the global coordinates of the display. Let the direction of the display be d.

In order to rotate the direction of the fly's heading to the direction of the display, $\mathbf{f}$ must be rotated to $\mathbf{d}$.

Figure 4.2: Rotating the observer's heading to look directly at the screen.
As illustrated in Figure 4.2, the same rotation applied to the observer's heading is also applied to the target's relative positions. For the code used in 4.1. Data Validation and PreProcessing and 4.2. Trajectory Reconstruction and Heading Estimation, see Appendix A. Code.

### 4.3. Simulation

As of present, the code prints the relevant data to CSV to be imported into the 3D Target and Starfield FlyFly stimuli. For illustration, Figure 4.3 shows how the data is ready from the code, but has to be input into the 3D Target stimulus.

Image removed due to copyright restriction.

Figure 4.3: Data from the code ready to be input into the 3D Target stimulus, which has to first be initialised (Henriksson 2010b).

## 4. Methods

However, this involves changing the working directory if the stimulus code is located in a different folder to the FlyFly directory, opening up the layer manager, and inputting the appropriate number of trials. The user must then copy the data from each of the spreadsheets into FlyFly.

A far more convenient solution would be to have a stimulus accessible from the FlyFly main menu, that imports the data from the CSVs directly without needing extra setup. This must also retain the option of including background optic flow, which can presently be done by using the 3D Target stimulus alone sans Starfield. Including the code as a FlyFly stimulus would also then allow the capture frequency to be set as a stimulus setting, without requiring prompting every time the code is run.

It is also important to note that in display of the background optic flow, simultaneous rotations are prohibited. This is due to the mathematical implementation of rotation within the code, and changing this method would allow for simultaneous rotations.

It was noted that any rotation can be decomposed into a sequence of rotations about the three orthogonal axes (Liu et al. 2012), however, for the purposes of display, rotation was cut to only about one axis. It was decided that yaw would be used for changes in X , alongside lift and thrust for changes in $Y$ and $Z$ respectively. This is in line with hoverfly flight exhibiting yaw saccades (Geurten \& Egelhaaf 2010; Land 1992). As a result, the reconstructions feature mainly translational optic flow, with some rotational components.

Another point to note is that the rotations used to align the heading with the $z$-axis are not physical rotations, and so do not produce rotational optic flow. These are mathematical rotations.

As the drawing uses the 3D Target and Starfield stimuli, the culling and clipping criteria apply. Off-screen targets are not drawn, nor are targets too close to the screen. This is a result of the glFrustum algorithm used in 3D projection. Objects that are too far away are clipped as they would otherwise be indistinguishable (Power 1996). This limit is set in the code, at 200 cm . Additionally, objects behind or too near to the eye are clipped (Power 1996). Again, this limit is set in the code, but also depends on the resultant dot size. This is in turn a factor of the graphics card used, and the limit set in the code is 6 cm . This also takes into account the standard experimental distance of the fly from the screen at 7 cm , although this too can be adjusted in the code.

For the purposes of this experiment, a variable was recorded to keep track of when the target would have been visible to the observer, ignoring the culling and clipping algorithms. This does not take into account the actual visual capabilities of the insect, considering hoverfly eyes can only resolve between 1 to 2 degrees (Henriksson 2010a). A dot of radius 1 cm , the default minimum dot size, at 200 cm , the default far clipping plane, would subtend an angular size of approximately 0.6 degrees, and so would be indistinguishable. Hence this method is only an approximation for foveation.

## 4. Methods

### 4.4. Determination of Pursuit

Pursuit is not clearly defined. Gibson (1957) defines pursuit as being the process of maximising the optical size of a target in the observer's field of view. On this basis, the target visibility variable recorded in 4.3 . Simulation was used as a factor in determining whether or not an interaction was a pursuit. When chasing a target moving at speed, animals can either follow at a higher speed in order to catch up, or attempt to intercept the target's path (Fabian et al. 2018).

Male hoverflies use a deviated pursuit strategy when chasing females, maintaining the perceived target position at a constant non-zero angle from straight ahead (Fabian et al. 2018). Hence, simulations based on data taken from male hoverflies pursuing females should show the observer attempting to keep the target at a constant non-zero angle from straight ahead.

Pursuit was determined according to the footage of the interactions, giving a simple 1 or 0 for likely to be a pursuit or not. The MATLAB Regression Learner toolbox was then used, with input as the proportion of the interaction that the target was visible, along with the number of frames between the target being visible. The target speed was also used as a factor, as this was calculated from the relative distance between the observer and target.

The average change in target speed was used to represent the change in distance between observer and target from frame to frame, and so a more negative number would suggest an overall closing of distance. 44 of 344 datasets were chosen at random as test sets, with the remaining 300 datasets left as training sets, giving a ratio of test sets to training sets of 0.147 .

## 5. Results

## 5. Results

As outlined in 4. Methods, 16 of the 106 datasets were invalid and so could not be further processed for testing. Similarly, after processing datasets to prepare input for the simulation, 52 of the 360 processed trajectories contained not-a-number (' NaN ') values. These NaN values cause the simulation to crash as they are unsupported in cells in MATLAB, and so they were edited out of the trajectories, skipping frames with NaN values.

The simulations were still run with these trajectories, and the data recorded as if the trajectories were unedited. Table 5.1 lists the trajectories that had NaN values edited.

Table 5.1: Trajectories from which $N a N$ values were removed in order to allow the simulation to not crash.

In addition to these 52 trajectories that could be edited, there were 12 more trajectories that consisted entirely of NaN values. The simulation could not be run at all using these trajectories, hence they were deemed invalid. These, too, were discarded. It is unclear what caused these trajectories to contain NaN values, and even more unclear what caused the 12 trajectories to be entirely invalid. Table 5.2 lists the trajectories that consisted entirely of NaN values.

As a result, only 348 trajectories could be used in simulations. Of these, 296 were unedited. However, although the datasets were valid for simulation, 70 of 348 trajectories resulted in the simulation encountering an error. These errors occurred at the end of the simulation, and seemed to be only an error in counting the number of frames dropped in simulation, although the cause is again unclear. Hence, these trajectories were also used in analysis, but tagged as having failed. Table 5.3 lists the trajectories which led to a failed simulation.

At this point, all data had been collected from simulation. See Appendix B. Summary of Results for a full table of results.

Kruskal-Wallis one-way ANOVA tests were then conducted on the datasets, to determine the homogeneity of the population. The first test considered the 348 datasets as a whole, and found it significantly unlikely that the datasets came from the same population ( $p<$ 0.001). All subsequent Kruskal-Wallis tests found each of the considered datasets to be unlikely to come from the same population. These findings were all at $\mathrm{p}<0.001$ except for those testing datasets using the line of sight method for the observer being matrix 1 (obs0los; vide 4.2. Trajectory Reconstruction and Heading Estimation). This finding was at $p<0.05$. See Appendix C.1. Kruskal-Wallis for a fuller description of the results of the Kruskal-Wallis tests.

However, Kruskal-Wallis tests for equality of medians, with the assumption made that the distributions were the same. With the null hypothesis being rejected, the medians were found to be unequal, hence the conclusion that at least one if not several of the many datasets considered did not come from the same population.

For a more powerful analysis, Conover-Iman pairwise tests with Bonferroni correction were then used. When the entire dataset was considered as a whole, 627 of 58996 comparisons were found to be significant, i.e. approximately $1.1 \%$ of datasets were found to significantly be unlikely to come from the same population.

Comparisons within methods gave differing results. The direction of motion method found 489 of 14706 (approximately $3.3 \%$ ) comparisons to be significant, whereas the line of sight method found only 51 of 14706 ( $0.3 \%$ ) comparisons to be significant.

In line with the finding from the Kruskal-Wallis tests that obs0los had the least significant rejection value of all comparisons, the Conover-Iman test found all of the data from this group to support the null hypothesis. Hence, this dataset can be said to be homogeneous. Because of this homogeneity in results from inputs that should be part of the same set, the method can be suggested to be consistent.

In contrast, the direction of motion method applied to the same set of trajectories returned 98 of 3655 ( $2.7 \%$ ) of comparisons as significant. For comparison, the same two methods applied to the observer as matrix 2 found 40 of 3655 (1.1\%) and 185 of 3655 (5.1\%) respectively to be significant. When considering the group of trajectories where the observer was set as matrix 1 as a whole, 114 of $14706(0.8 \%)$ were found to be significant, compared to the obs1 population, finding 324 of 14706 ( $2.2 \%$ ) of comparisons to be significant. See Appendix C.2. Conover-Iman for the full results of the Conover-Iman tests.

Overall, setting the observer as matrix 1 gave more consistent results regardless of method of heading estimation. That being said, all datasets are fairly homogeneous, with all except the obs 1 dom population having at least $95 \%$ supporting the null hypothesis.

As outlined in 4.4. Determination of Pursuit, the MATLAB Regression Learner toolbox was used to model an algorithm for determining pursuit, based on the factors listed previously. See Appendix D. Determining Pursuit for a full table of the data supplied to the algorithm. The algorithm did not perform well, potentially due to the binary value of the output it was trying to predict. This will be discussed further in 6.1. Analysis. Of the four learning methods selected by the toolbox, linear regression had the lowest RMS error, of 0.49827. However, this is still very high. Figure 5.1 shows the response plot from the regression learner, with the supplied binary values of pursuit in blue, and the predicted values in yellow.

Figure 5.1: Response plot from the regression learner.

## 5. Results

As can be seen in the response plot in Figure 5.1, the regression learner was fairly conservative, with most of its responses sitting around the median of 0.56 . In fact, when the algorithm was applied to the 44-member test set, none of the values were below 0.5 , as shown in Table 5.4. This meant that rounding could not be used to differentiate between what it had decided was a pursuit and what was not.

Table 5.4: The results of applying the linear regression to the test set.

## 5. Results

| Trajectory <br> ID | Pursuit | Value determined by <br> linear regression |
| :---: | :---: | :---: |
| 080obs1dom | 1 | 0.540426708263338 |
| 034obs0los | 0 | 0.564925293786210 |

If the value given by the regression learner is to be interpreted as a probability of whether or not a pursuit, the regression learner can be said to mainly determine pursuits as having an essentially equal possibility of being or not being a pursuit. The conservativeness of the regression learner can be seen more clearly in Figure 5.2, where the data clearly bunches near 0.5 , particularly for data that was tagged as not being a pursuit.

Figure 5.2: Predicted response vs. true response, as determined by the regression learner.
The equation of the line of best fit, shown in Figure 5.2, suggests that only the pursuit variable has an effect on whether or not the interaction is a pursuit. With such a small intercept, and a slope of 1 , the line of best fit will predict a 1 when the pursuit variable is 1 , or 0 if not.

## 5. Results

When the algorithm was applied to the test set, similar results were produced. Figure 5.3 shows these results.

Figure 5.3: Using the linear regression algorithm on the test set.
Again, the data bunches around the median, indicating an equal probability of pursuit.

## 6. Discussion

### 6.1. Analysis

As outlined in 5 . Results, the homogeneity of all but one of the datasets is remarkable. This suggests that the methods used are at least somewhat robust. The fact that the consistency was markedly higher for setting the observer as matrix 1 suggests that this data itself was more consistent. As the films always involved hoverflies interacting with other insects, be they other hoverflies or insects of other species, it could be reasonable to assume that the hoverfly was always tagged as matrix 1 . As a result, data from matrix 1 across the interactions would exhibit a great degree of self-similarity, especially compared to that of matrix 2 , where the species of insect may differ between interactions. Indeed, in some interactions the other participant was not an insect at all, but a bead on a string.

However, although the results from the statistical tests were impressive, the results from the linear regression were not. Whether this was a function of the data itself, or of the methods used to manipulate the data, is unknown. However, although some of the interactions were tagged as likely to be pursuits according to the footage, Thyselius et al. (2018) found it unlikely that any of the interactions were deliberate pursuits, according to the characteristics of the flights. It would be interesting to investigate the effect of changing the pursuit variable from being a binary yes or no to a probability or likelihood.

That being said, despite the intended use of the determination of pursuit as a metric for validation of the methods, the inconclusive results of the regression make it hard to discount the comparatively stronger results of the statistical tests.

In particular, the finding that the group of trajectories arising from matrix 2 data treated with the line of sight method were all significantly likely to come from the same population lends support to the validity of applying this method to this group of data.

From a deliverables point of view, the end product meets the original specifications. The program takes input in the form of 3D position datasets - although at this point they must be of a specific format - and estimates the heading along the trajectory in order to create a simulation of the flight as would have been experienced by the original fly. The user can select which insect will be at the centre of motion, and by using the FlyFly assets, experimental variation can be implemented.

### 6.2. Limitations and Improvements

The data used in this project had its limitations, as has been outlined in 1.1 Background, 2.1. Tracking Insect Flight, 2.4. Trajectory Reconstruction and Flight Simulation, and 2.5. Display of Optic Flow. In textured surroundings such as those filmed by Thyselius et al. (2018), increasing the resolution of the image generally increases the amount of information available, in contrast to images of "urban" scenes, with more visually uniform objects (Brinkworth 2009). In this sense, increased image resolution for caged flights would have little effect on the information provided, whereas higher resolution for the interactions filmed would give more information.

The data collection built upon the experimental setup used by Wardill et al. (2017), although in those experiments, cameras were placed at right angles to the anteriorposterior body axis of the fly, allowing for the pitch and yaw angles of the body to be measured. Additionally, a piece of white fabric was used as a backdrop in all experiments to improve contrast, even in the wild. Despite the similarities between the experimental setups, these differences that are also present have a great impact on the information contained in the data collected. If new data were to be collected for use with this program, ideally it should also contain information on the heading of the insects involved in the interactions, without needing to make an estimate.

There were further limitations in the way that the simulation was performed as part of this experiment. As outlined in 4.3. Simulation, rotational movements were vastly simplified. However, this does not necessarily accurately reflect free insect flight, as flight control depends on control of roll and pitch in addition to yaw (Goulard, Vercher \& Viollet 2016). These two components of rotation were removed for simplification, but in future should be implemented if the rotation algorithm can be adjusted to make this possible.

An additional limitation was also found in the simulation. The default dot size used to draw targets on the screen is a 1 cm radius, being the lowest that this size could be set to. This size is used as the true size of the object, and is projected onto the screen accordingly. However, this is very likely to not be representative of the true size of the targets involved in the actual pursuits. That being said, this size was chosen as sizes any larger were not supported by the graphics card. As a result, simulations would crash irretrievably.

### 6.3. Future Work

Originally, a control strategy was to be developed to determine the heading based on the characteristics of the flight. Much research has been done to attempt to find algorithms to adequately describe the flight behaviour of insects. Fry et al. (2009) mentioned a PID control scheme underlying the control of flight altitude in honeybees. Franceschini, Ruffier, and Serres (2007) described an extremely simple method by which insects control their flight speed and altitude. It was proposed that insects use a simple ratio between ground height and ground speed during cruising flight, in order to maintain a constant optic flow experienced (Lawson \& Srinivasan 2017). This also has the effect of controlling their air speed, effected by changing the pitch of their bodies.

Fabian et al. (2017) found proportional navigation sufficient to explain both timing and magnitude of steering responses exhibited by Holcocephala robber flies and Coenosia killer flies in pursuit. The gain constants and delays describing the proportional navigation controllers differed between species. It was suggested that other insects may also use proportional navigation with species-specific parameters. Future work on this project could investigate tuning a proportional controller to hoverflies, based on their trajectories, as well as ground height and ground speed, in order to determine their heading and thus optic flow.

Physical constraints about the actions animals take can also be used as information to constrain possible poses (Arnab, Doersch \& Zisserman 2019).

## 7. Summary

There is further work still to be done on this project, with improvements that can be made in order to meet the original goals. In particular, investigating a control strategy may ease the process of estimating the heading of the hoverflies. This could be used to improve the performance of the algorithm developed with regression learning.

If new data at higher resolutions could be sourced, computer vision could be investigated. A ground truth could then be provided for the heading, or alternatively, a ground truth could be estimated, as mentioned in 2.7. Heading Estimation and Machine Learning.

Altogether, however, despite the challenges faced throughout this project, in particular the limitations placed upon the project due to the data provided and the tools to be used, a program was developed that meets the original specifications.

## Appendix A. Code

This appendix contains the code used in 4.1. Data Validation and Pre-Processing and 4.2. Trajectory Reconstruction and Heading Estimation. This code is the main deliverable of the project, and takes the datasets provided by Thyselius et al. (2018) as input. At present, the validation step relies on the datasets being in the same, uniform, format.

```
%% 0. Clear all
clear all
%% 1. Navigate to desired dataset
% Opens user interface to select the dataset to be worked on
[trajectory, filepath] = uigetfile('*.mat');
% Loads the selected dataset into the MATLAB Workspace
load([filepath,trajectory])
%% 2. Check dataset is valid
% First, check that the cell has two matrices
if size(all_3Dcordinates,2) == 2
    % Next, check that the matrices are the same size
    if size(all_3Dcordinates{1}) ==
size(all 3Dcordínates{2})
            % Finally, check both matrices have 3 rows
            if size(all_3Dcordinates{1},1) == 3
                % Contiñue if all the above are satisfied
            else
                msgbox('Selected dataset is invalid: matrices do
not have three rows.', 'Invalid Value', 'error')
            return
            end
        else
            msgbox('Selected dataset is invalid: matrices are
not of the same size.', 'Invalid Value', 'error')
            return
    end
else
    msgbox('Selected dataset is invalid: cell does not
contain two matrices.', 'Invalid Value', 'error')
    return
end
% Here is where you could also include an interactive option
for the user
% to adjust the datasets so that they are valid, as well as
a way to check
% if the selected dataset has already been processed
%% 3. Select leader and pursuer
% Prompt user to choose which matrix is which
```

```
warning('off','MATLAB:questdlg:StringMismatch') % Suppress
warning about default button
% Format: questdlg(quest,dlgtitle,btn1,btn2, (btn3), defbtn)
prompt = questdlg(['Which matrix represents the pursuing
fly? The perspective ' ...
    'of this fly will be used as the basis of the
reconstruction and simulation.'], ...
    'Select leader and pursuer','1','2','defbtn'); %
Pressing Enter will not close dialog box
observerFlag = str2num(prompt)-1;
%% 4. Convert positions from absolute to relative
% Both observer and target's original motion will be saved
for later use
observerPositions = all_3Dcordinates{observerFlag+1};
targetPositions = all_3Dcordinates{2-observerFlag};
% Reverse direction of z-axis to match FlyFly's definition
observerPositions(3,:) = -observerPositions(3,:);
targetPositions(3,:) = -targetPositions(3,:);
% This line of code will create a matrix with relative
positions depending
% on which matrix was selected as the observer. The vectors
also represent
% the direct line of sight between the observer and the
target at each frame
targetRelativePositions = targetPositions -
observerPositions;
%% 5. Get direction of motion between frames
% Vector at each frame representing the direction of motion
to next position
for m=1:length(targetPositions)-1
        for n=1:3
        % Change in position between trials
        targetMotion(n,m) = targetPositions(n,m+1) -
targetPositions(n,m);
        observerMotion(n,m) = observerPositions(n,m+1) -
observerPositions(n,m);
    end
end
%% 6. Choose how to rotate positions
% Heading of fly must be aligned with the z-axis in order to
display with
% FlyFly -> the heading must first be chosen
alignmentMethod = questdlg(['What would you like to align
the pursuer''s heading ' ...
    'with?'],'Select heading alignment','Direction of
Motion','Line of Sight', ...
    'Choose for me','defbtn');
```

```
% Once user has selected how they want to align the
pursuer's heading,
% set this so that the motion can be rotated accordingly
switch alignmentMethod
        case 'Direction of Motion'

    observerHeading = [];
end
%% 7. Algorithm for estimating most suitable heading
if isempty(observerHeading)
    % algorithm goes here
end
%% 8. Rotate heading to align with z-axis
% This code uses the angle-axis method to create a rotation
matrix, aligning
% the selected heading with the z-axis. This rotation is
then applied to the
% relative positions of the target.
zAxis = [0 0 1];
% Does not process entire matrix so matrix dimensions do not
exceed the loop index
for n = 1:length(observerHeading)-1
    % Use cross-product to get axis of rotation
    xprod{n} = cross(zAxis,observerHeading(:,n));
    % Use dot-product to get angle of rotation
    dprod(n) = dot(zAxis,observerHeading(:,n));
    theta(n) = acos(dprod(n)/norm(observerHeading(:,n)));
    % MATLAB uses Rodrigues' formula here
    rotationVector{n} = theta(n)*xprod{n};
    rotationMatrix{n} =
rotationVectorToMatrix(rotationVector{n});
    % Apply rotation to observer's motion for display of
optic flow
    rotatedObserverMotion{n} =
rotationMatrix{n}*observerMotion(:,n);
```

```
    % And to target's relative positions
    rotatedTargetPos{n} =
rotationMatrix{n}*targetRelativePositions(:,n);
end
% Convert positions into a usable format
rotatedTargetPos = cell2mat(rotatedTargetPos);
rotatedObserverMotion = cell2mat(rotatedObserverMotion);
%% 9. Calculate velocity
% Target moves in straight line therefore velocity is
calculated from Euclidean
% distance moved between each position coordinate and the
time between capture
% of each position coordinate
for k = 1:length(rotatedTargetPos)-1
    targetDistance(k) = sqrt(rotatedTargetPos(1,k)^2 +
rotatedTargetPos(2,k)^2 + rotatedTargetPos(3,k)^2);
    observerDistance(k) = sqrt(rotatedObserverMotion(1,k)^2
+ rotatedObserverMotion(2,k)^2 +
rotatedObserverMotion(3,k)^2) ;
end
% % Check with user what the coordinate capture frequency is
% trialRate = inputdlg({'At what frequency were the position
coordinates captured (times per second) ?'}, ...
% 'Confirm position coordinate capture
frequency',1,{'30'});
% trialRate = str2num(trialRate{1});
trialRate = 30;
% Time between each coordinate capture is reciprocal of
capture frequency
interTrialTime = 1/trialRate;
% Calculate target velocity based on this information
targetVelocity = targetDistance/interTrialTime;
observerVelocity = observerDistance/interTrialTime;
%% 10. Save values for 3D Target to CSV
% 3D Target takes positions in the form of azimuth,
elevation, and distance.
% The coordinate system in the FlyFly guide was used in this
conversion method,
% converting the XYZ positions to az/el/r. Angles are
specified in degrees.

% 13. Import values directly into FlyFly
```

## Appendix B. Summary of Results

This appendix contains a summary of the results of 4.3 . Simulation, noting which datasets and trajectories were invalid or otherwise of note. As can be seen in the table, some datasets had NaN values that were edited and resulted in a reconstruction that failed, whereas others did not lead to an error. Likewise, some failed reconstructions resulted from trajectories that did not previously have NaN values.

Table B.1: A summary of the results of 4.3. Simulation.

## Appendix C. Results of Statistical Tests

This appendix contains the results of the statistical tests applied to the results to determine the consistency of the methods described in the main body.

## Appendix C.1. Kruskal-Wallis

This section contains the results of the Kruskal-Wallis tests. First, the entire dataset was compared as a whole, then the datasets within the two methods (direction of motion, line of sight), were compared. Next, datasets according to different selection of observer were tested, and finally, data within the four individual groups was compared.

Table C.1.1: Results from the Kruskal-Wallis test applied to the dataset as a whole.

| Source | SS | df | MS | Chi-sq | Prob>Chi-sq |
| :--- | :--- | :--- | :--- | :--- | :--- |
| Groups | $2.10933 \mathrm{e}+10$ | 343 | $6.14966 \mathrm{e}+07$ | 2180.69 | $2.96135 \mathrm{e}-264$ |
| Error | $9.54058 \mathrm{e}+10$ | 11701 | $8.15365 \mathrm{e}+06$ |  |  |
| Total | $1.16499 \mathrm{e}+11$ | 12044 |  |  |  |

Table C.1.2: Results from the Kruskal-Wallis test applied to the DOM dataset.

| Source | SS | df | MS | Chi-sq | Prob>Chi-sq |
| :--- | :--- | :--- | :--- | :--- | :--- |
| Groups | $2.90836 \mathrm{e}+09$ | 171 | $1.70079 \mathrm{e}+07$ | 1655.64 | $4.08333 \mathrm{e}-241$ |
| Error | $6.4194 \mathrm{e}+09$ | 5139 | $1.24915 \mathrm{e}+06$ |  |  |
| Total | $9.32776 \mathrm{e}+09$ | 5310 |  |  |  |

Table C.1.3: Results from the Kruskal-Wallis test applied to the LOS dataset.

| Source | SS | df | MS | Chi-sq | Prob>Chi-sq |
| :--- | :--- | :--- | :--- | :--- | :--- |
| Groups | $1.60167 \mathrm{e}+09$ | 171 | $9.36647 \mathrm{e}+06$ | 507.01 | $5.39091 \mathrm{e}-35$ |
| Error | $1.96682 \mathrm{e}+10$ | 6562 | $2.99729 \mathrm{e}+06$ |  |  |
| Total | $2.12699 \mathrm{e}+10$ | 6733 |  |  |  |

Table C.1.4: Results from the Kruskal-Wallis test applied to the obs 0 dataset.

| Source | SS | df | MS | Chi-sq | Prob>Chi-sq |
| :--- | :--- | :--- | :--- | :--- | :--- |
| Groups | $1.77221 \mathrm{e}+09$ | 171 | $1.03638 \mathrm{e}+07$ | 821.75 | $1.07718 \mathrm{e}-85$ |
| Error | $1.03006 \mathrm{e}+10$ | 5427 | $1.89802 \mathrm{e}+06$ |  |  |
| Total | $1.20728 \mathrm{e}+10$ | 5598 |  |  |  |

Table C.1.5: Results from the Kruskal-Wallis test applied to the obs 1 dataset.

| Source | SS | df | MS | Chi-sq | Prob>Chi-sq |
| :--- | :--- | :--- | :--- | :--- | :--- |
| Groups | $3.6222 \mathrm{e}+09$ | 171 | $2.11824 \mathrm{e}+07$ | 1347.9 | $7.94924 \mathrm{e}-182$ |
| Error | $1.36974 \mathrm{e}+10$ | 6274 | $2.1832 \mathrm{e}+06$ |  |  |
| Total | $1.73196 \mathrm{e}+10$ | 6445 |  |  |  |

Table C.1.6: Results from the Kruskal-Wallis test applied to the obs 0 dom dataset.

| Source | SS | df | MS | Chi-sq | Prob>Chi-sq |
| :--- | :--- | :--- | :--- | :--- | :--- |
| Groups | $2.33105 \mathrm{e}+08$ | 85 | 2742416.6 | 696.85 | $7.92246 \mathrm{e}-97$ |

## Appendices

## Appendix C.2. Conover-Iman

The Conover-Iman results were far too large to attach, with one table having almost 60000 rows, and so are available online here instead:

## https://drive.google.com/drive/folders/1oVZnaqdoAOR2U3DOMD18mzhW6yPe3U 6

In order, the files contain the results of the Conover-Iman tests applied to the following populations:

1. collatedTest: All 344 valid trajectories collated as a whole ( 58996 comparisons)
2. domTest: All trajectories treated with the DOM method (14706 comparisons)
3. losTest: All trajectories treated with the LOS method (14706 comparisons)
4. obsOdomTest: All trajectories from the obs 0 dom population ( 3655 comparisons)
5. obsOlosTest: All trajectories from the obs 0 los population ( 3655 comparisons)
6. obsOTest: All trajectories with observer set as matrix 1 (14706 comparisons)
7. obs1domTest: All trajectories from the obs 1dom population ( 3655 comparisons)
8. obs1losTest: All trajectories from the obs1los population (3655 comparisons)
9. obs1Test: All trajectories with observer set as matrix 2 ( 14706 comparisons)

## Appendices

## Appendix D. Determining Pursuit

This appendix contains the data used to supply the regression learner. Trajectories were tagged as pursuit or not, according to the footage. 300 of the 344 datasets were selected at random as training data, and the remaining 44 were left as test sets. The training data was then input to the regression learner to build an algorithm.

Table D.1: Data supplied to the regression learner.

| Trajectory ID | Percentage visible | Average \# frames between visibility | Average change in speed | Pursuit |
| :---: | :---: | :---: | :---: | :---: |
