Abstract

This thesis investigates a design development and performance improvement of Synchronous reluctance motor with the line-start capability comparable with an induction motor. A three-phase induction motor with the rated output power of 20kW is selected as a benchmark. The aim is to introduce the synchronous reluctance motor designs with the same starting capability of the induction motor under the study. The proposed synchronous reluctance motors have the same stator design as the induction motor but the differences are in the rotor. Since the synchronous reluctance motors are not self-starting. The proposed rotor designs are equipped with the cages and successfully their performances are improved. In the proposed models, two different hyperbolic-line and hyperbolic curve shape of flux barriers are introduced. The performances of these models are further improved by adding the permanent magnets to the rotor flux barriers. All the proposed motor designs are simulated and tested under different loading conditions in FEM software. The performance of the designed motors is satisfactory in both steady-state and starting conditions. The proposed motor designs outperform the induction motor in terms of power factor and efficiency with up to 10% of increment. The outcome of this research is expected for the future investigation of the new configurations of the line-start motors with higher efficiency and power factor.

Declaration of Academic Integrity

'I certify that this thesis does not incorporate without acknowledgment any material previously submitted for a degree or diploma in any university; and that to the best of my knowledge and belief it does not contain any material previously published or written by another person except where due reference is made in the text.'

Chapter 1

Introduction

1.1 Background

In today's era, the main aim is to do the sustainable energy development with the use of highly efficient products as well as more use of the renewable energy also appreciated. By looking in the present scenario, at least 40 to 45% of electrical energy has been consumed by electrical motors with nearly 75% efficiency [1]. The rest of the energy has been wasted in the different losses and the emission of CO₂. As induction motor is the most commonly used motor for all industrial application and for other household purpose. In addition to that to develop a motor with low cost and simple construction is the biggest challenge. Slip in the motor is the major reason of the limited efficiency and losses can be another reason for the limited efficiency.

These types of economical and efficient motors introduced with the use of permanent magnets in the rotor construction. So, before developing the new design it is very important to study the consumption of electrical energy by electrical motors and different efficiency standards of different countries.

Globally, the electricity consumption in the world is 21.9 trillion KWh and it is predicted for 84% of the increment by 2015. From the total of that energy 42% of the electricity is consumed by industries and 2/3 of this is consumed by electric motors which is 28% which is shown in the figure 1. Among those all motors 50% of the motors are installed in USA, EU and China [2].

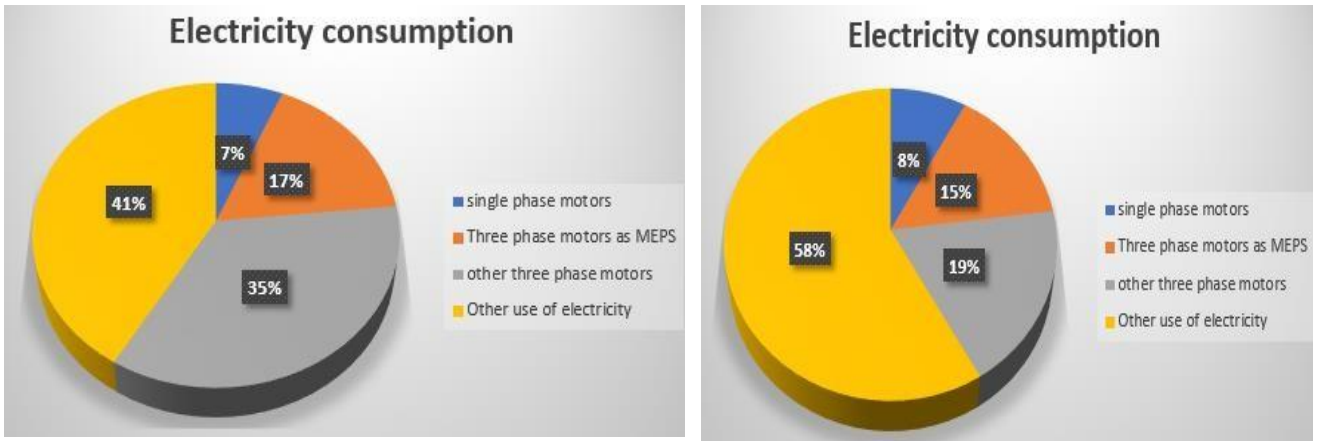

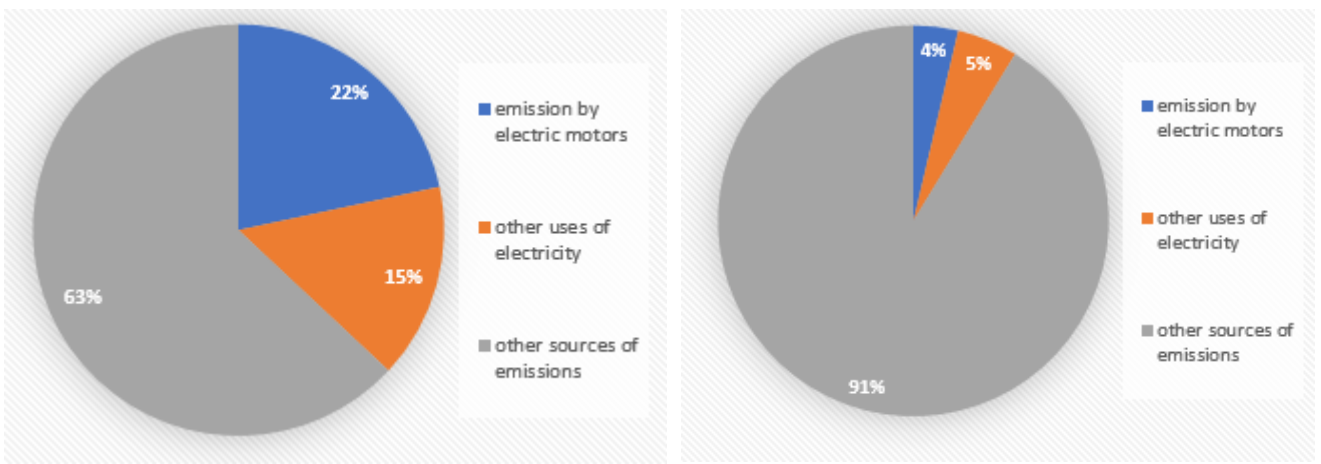

Fig 1 Global consumption of the electricity [2].

Electric motors are widely used in the world. But, specifically 59% of the electrical energy is consumed by different motors in Australia [3]. The pie-chart (a) below, shows the consumption of electricity in Australia per year from the total produced electricity. And the pie-chart (b) shows the electricity used by motors in New-Zealand, which is noted 42% of the total energy in figure 2,

(a) (b)
 Fig 2 Electricity used by motors in Australia (a) and New-Zealand (b). [3].

Because of these much use of the electric motors the emission of CO₂ can be the important subject to consider to the sustainable development in terms of an environment. Here, are some statistics given in figure 3 on the CO₂ emission in Australia and New-Zealand.

(a) (b)
 Fig 3 CO₂ emission caused by electric motors in Australia (a) and New-Zealand (b) [3].

So, to overcome this kind of serious threat to the environment, there should be some standards in the production of electrical motors. So, IEC (International Electrotechnical Commission) has introduced the international efficiency standards. Same as that, Australian government has implemented MEPS (Minimum efficiency performance standard) in 2011 [4]. NEMA has also introduced the efficiency standards NEMA MG 1: for motors and generators [5]. So, the table below shows the Australian minimum efficiency standard for the different rating of the motors.

Table 1 Minimum efficiency standard for three-phase electric motors in Australia and New-Zealand [6].

Rated output kW	Minimum efficiency %			
	2 pole	4 pole	6 pole	8 pole
0.75	78.8	80.5	76.0	71.8
0.75	78.8	80.5	76.0	71.8
1.1	80.6	82.2	78.3	74.7
1.5	82.6	83.5	79.9	76.8
2.2	84.1	84.9	81.9	79.4
3	85.3	86.0	83.5	81.3
4	86.3	87.0	84.7	82.8
5.5	87.2	87.9	86.1	84.5
7.5	88.3	88.9	87.3	86.0
11	89.5	89.9	88.7	87.7
15	90.3	90.8	89.6	88.9
18.5	90.8	91.2	90.3	89.7
22	91.2	91.6	90.8	90.2

Also, European union has introduced minimum efficiency standards, which is illustrated below in the figure 4.

Fig 4 Efficiency standard for 4-pole, 50Hz low voltage electric motor [7].

Within today's data, the lowest class of efficiency IE3 has been produced in the European Union. With the new derivative of the European Union, there are different efficiency classes has been revealed such as, IE1 (Standard Efficiency), IE4 (Super Premium Efficiency). The whole new IE5 (ultra-premium efficiency) has been under research. Here, the necessity to design these models because, the aim is to develop highly efficient motor with cheaper option and to improve the performance of the motor by doing changes with rotor design.

1.2 Problem statement

With the major utilization of an induction motor in the industries and household purpose, these induction motors have major losses. These losses result in lower efficiency of the electrical machine and it can contribute in the emission of Co₂, which could be the reason for the environmental problems such as global warming and it is not a better way for the sustainable development of an environment.

Losses in the IM caused by the copper winding in the rotor part, friction while rotating, electrical losses. But, losses which are produced because of rotor winding called copper losses. So, these copper winding can be removed from the rotor and by this way the rotor copper losses can be reduced. Also, for better torque density and higher efficiency permeant magnets can be accommodated.

From the previous studies of thesis "start capability of industrial synchronous motor with high efficiency", it was observed that the majorly used induction motor can be replaced by the high efficient synchronous motor with the self-starting property. The idea was raised in the mind to do the further investigation with the steady state and transient operations.

As, it was also noticed that the synchronous reluctance motor has less losses compared to the induction motor because of less material consumption and not having copper winding in the rotor part. Also, it has more advantages such as less heating, higher efficiency, better torque density. So, the synchronous reluctance motor was taken for this research.

There are certain developers who developed the synchronous reluctance motor such as ABB and SIEMENS. These motors fulfil all the requirements such as higher efficiency, low cost. But, these motors are not self-starting. So, there is a need of any external drive to start those motors. To overcome this problem, hybrid construction of motor should be required. So, these self-starting properties of the motor could be achievable by combining the induction motor and synchronous motor. So, with this hybrid arrangement of the motors both higher efficiency and self-starting of the motor can be achieved without any external source.

This type of motor can be utilized for the different constant speed application in industries and it can replace the small and the medium size of the motor. Which results an overall reduction of Co2 emission every year.

So, the induction motor is considered as a benchmark model of study, and additional two designs of line-start synchronous reluctance motors are introduced with different rotor configuration.

In addition, for more better results and better performance one of the possible alternate option is to insert the permanent magnets in the hybrid constructed motor with cage winding. So, the magnets were accommodated in the air barriers of the rotor. With these specifications, the all new line-start permanent magnet synchronous reluctance motor is introduced with again two different rotor configurations. These types of motors can start as an induction motor without any external source. Which excludes the cost of external drive so, still these models are cheaper option for the replacement of an induction motor.

For the optimization of the performance the additionally designed four different line-start synchronous reluctance motor and line-start permanent magnet synchronous reluctance motors are simulated and tested for steady-state analysis, transient analysis to test the performance of the operation and magneto static analysis is performed to obtain the magnetic quantities of the models and compared with the benchmark three-phase induction motor.

1.3 Objectives

- To study the specification of 20kW three phase induction motor with 4-pole and 50Hz configuration.
- To simulate and predict the performance of a three-phase induction motor as a benchmark design.
- To introduce the line-start synchronous reluctance motor comparable with the three-phase induction motor.
- To simulate the introduced designs of line-start synchronous reluctance motor with two different rotor configurations, without changing the stator of the motor.
- To improve the performance of the line-start synchronous reluctance motor, introduction to the additional two designs with the permanent magnets accommodated in the rotor flux barriers and design of line-start permanent magnet synchronous reluctance motor with the same curve and line shape of flux barriers.
- To simulate and analyze the newly introduced model to check the performance with different loading condition by performing steady-state, transient and magneto static analysis and

comparison with the benchmark model to validate the obtained results in terms of improvement in power factor and efficiency of the motor.

1.4 Methodology

In this research, the primary step was to study designing and simulating of electrical machine using Ansys Maxwell 2D. Software used in the research were ANSYS Maxwell 2D, RMXprt, because of its industrial standard accuracy. So, in the first step of the research, the 20kW , three-phase, 4-pole, 50Hz induction motor was selected for the parameter and specification study in RMXprt to obtain the design variable. After the study of the specification of the motor, it was designed in Maxwell 2D for the performance analysis by using the finite element method. This benchmark induction machine was taken from the previous paper. After the designing of induction motor, the performance results were obtained from the simulation of the model. And the modern design of the line start synchronous motor was predicted because of its bunch of advantages against induction motor. Again with help the parametric analysis the line-start synchronous reluctance motor was designed using Maxwell 2D. and it was simulated and the performance results were obtained in the form of graphs. In order to determine more efficient design and better performance again with the parametric analysis the design of line-start synchronous reluctance motor was modified. This modification was only kept limited to the rotor by adding the magnets in the flux barriers but the stator part is remained same in the whole research. These additionally designed two models of the line-start permanent magnet synchronous reluctance motor was simulated for the same magneto static, steady state analysis and transient analysis. At last all the obtained results were compared with the benchmark model and optimization of the better performance of the motor was validated in terms of power factor and efficiency. Here, the flow chart in the figure 5 shows the brief designing process of motors.

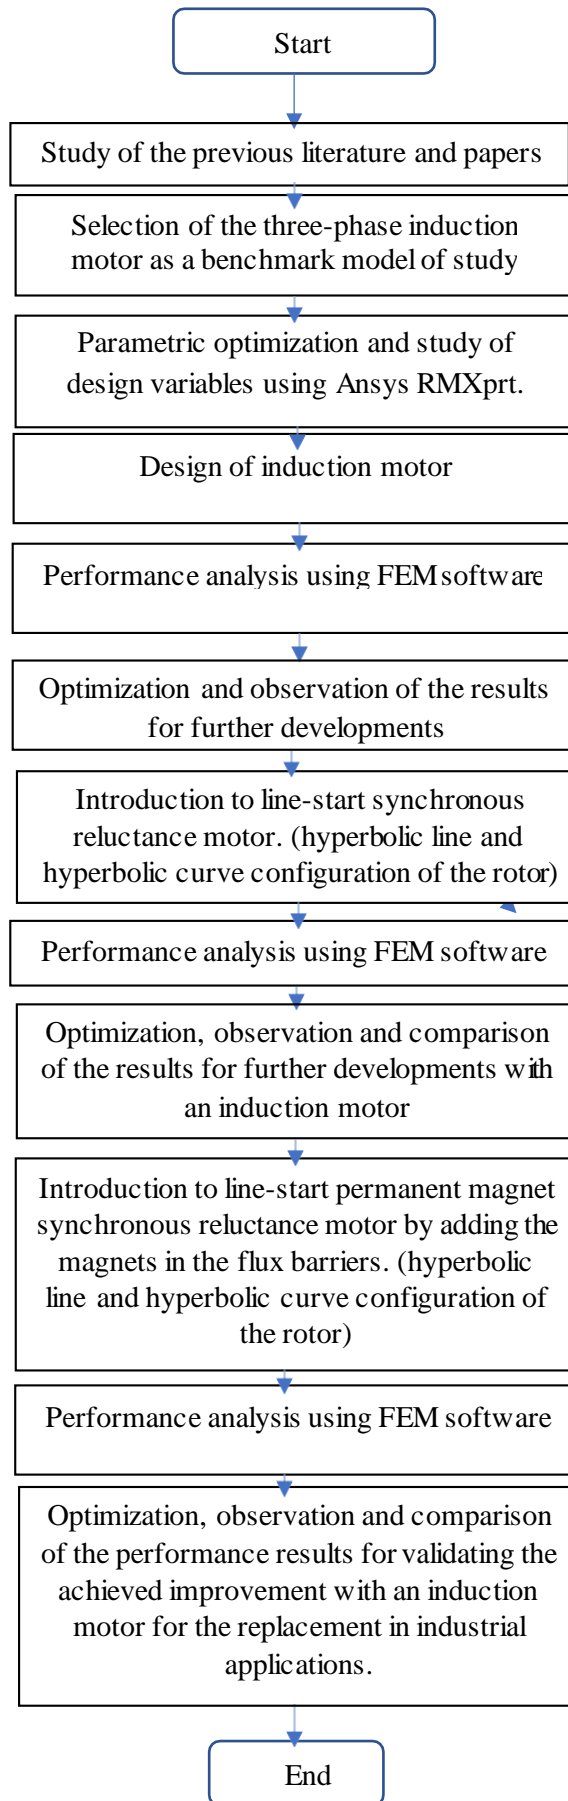

Fig 5 Flow chart of designing and simulation process.

1.5 Limitations and scope

In this research, designs were developed in 2D and most of the simulations are performed in Maxwell 2D. The limitation of this research is that, if all the models were designed in 3D, it becomes more computationally expensive nature. But, still in 2D design the radial flux machine gives better performance on the other side due to the limitation of the time Maxwell 3D is not used in this research because it takes more time and the storage space. In Maxwell 2D, there is not much difference in the designing and the accuracy of the results while simulating small and medium size machines. And due to the limitation of the device used, major results of the thesis are simulated in Maxwell 2D.

The experimental testing of the motor can be more expensive because of its fabrication cost and material cost. So, these models are tested analytically with the help of FEM and analytical software.

On the other side, the scope of this project includes the performance analysis and designing of the models for examine the effect of change in flux density within the newly constructed rotor parts of the line-start synchronous reluctance motor and the effect of flux linkage when the magnets are inserted. For the further testing, at least new combination of the magnet accommodation should be developed for simulation and it is expected for the better power factor and efficiency of the machine for the scope of the research.

1.6 Thesis outline

Chapter 1: Introduction

Chapter 1 consist of an overall background of the project. In this chapter, the problem statement, methodology, limitations of the project and further scope of the project has been described. The thesis outline is the last part of the chapter.

Chapter 2: Literature Review

Chapter 2 gives a literature review in which, the previous papers and researches used as the guiding lights of this research and some selected areas in which the best contribution can be made. It also includes the brief information on the different papers related to the line-start synchronous motor and line-start permanent magnet synchronous reluctance motor. Finally, this chapter ends with the gap statement with the information of gap from the previous research and the contribution to that researches.

Chapter 3: Design Aspects and Specifications

Chapter 3 stands for the design aspects and the specification used for designing the electrical machine. It gives the step by step evolution of the designing process of the motors. And this chapter ends with the proposed designs of line-start synchronous reluctance motor and line-start permanent magnet synchronous reluctance motor.

Chapter 4: Simulation parameters and Analysis

Chapter 4 elicits the information about the explanation of the software used to simulate the designed models and the simulation parameters used for this research and it also includes the magnetostatic analysis of the proposes models. In addition, this chapter also focus on the steady state and transient analysis of the designed models. This chapter ends with the results of the analysis.

Chapter 5: Results and Discussion

This chapter 5 includes the detailed description of the results. And it shows, how the purposed designed models outperform the induction motor. This chapter ends with the comparison of the results obtained from testing and simulation.

Chapter 6: Conclusion and Future Work

Chapter 6 shows the conclusion derived from the comparison of the results. And this chapter ends with, what future implementation can be done in the research in the future work based on the results of the project.

Chapter 2

Literature Review

2.1 Introduction

There are several researches carried out throughout the last 10 years. Because of different researches on electrical machine, there are different unique designs of the motors are invented. All of those new innovated designs carry its advantages and disadvantages. Basically, there is not any standard method decided for the design process or approach. But, there are several different paths for the optimization of designing the electric motor. In this chapter, the review starts with the discussion of the previous papers, which are contributing for the design of the synchronous reluctance motor also, it includes the different analysis methods used by the researchers in the designing of line start motor and permanent magnet assisted synchronous reluctance motor. In the second part of the chapter the research gap is illustrated.

2.2 Induction motor

There are vast range of papers that uses different methods of the electrical machine design. But, from all of them there are limited with the broad ideas of designing. Juha, Tapani and valeria [8] provides the huge theoretical background with the mathematical equations to design the rotating electrical machine. It also provides the huge amount of basic and detailed information for the different segments to focus on while designing the electric machine such as, winding of the machine, analytical calculation of flux lines, airgap, inductances in their book 'design of Rotating Electrical machines'.

Also, there is one more source that gives the actual ideas of designing the induction motor with the explanation of different useful parameters such as, in the construction part the stator and rotor design, shaft and frame design. Then selection of the flux density, estimation of the main dimensions, the length of machine, airgap length and the detailed information is provided including losses calculation and estimation of the performance of the induction motor written by K.G Upadhyay [9].

Jalila, Naourez, Mourad, Rafik and Moez [10] presents their study with the two assorted designs of the induction motor with two different topologies and the focus of the paper is specifically on the slot shape of the induction machine. The analysis used in this study to test the performance of the induction motor is finite element method. And also, tested the induction motor with different loading conditions. In conclusion, It was concluded that the round shape of the slots are better than the rectangle shaped rotor slots, which improves the sinusoidal flux lines.

Leonard, Alecsandru, Adrian, Margareta and Ovidiu [11] provide a good example of designing the induction motor and the performance analysis of the induction motor. The motor designed in this study is the high-powered motor with the rated output power of 631kW, 4-pole, 50Hz. The rotor used for the motor is the dual cage rotor which results decrease in the starting current and high pull-up torque. For designing of the motor finite element method is used to check the magnet circuit of the motor and flux

paths in the different areas. This study concludes with the better performance results as proposed low starting current and high pull-up torque.

Afaque and Vaibhav[12] gives the study on the investigation of the three phase induction motor using finite element method for the power quality improvement. The rotor winding of the induction is in focus in this study. Here, in this study the standard inductance motor is selected as a benchmark and with the different combinations of the material used in the rotor winding, two unique windings are invented. And for the rotor. The method used for the analysis is the same finite element analysis. This study concludes with the better power factor and the losses of the rotor has been reduced and the efficiency has made an improvement in the proposed design of the motor.

2.3 Line-start synchronous reluctance motor

In the design of line-start synchronous reluctance motor, there are several papers which provides a huge scope of designing aspects. So, in this type of motor, Samad, Mortaza and Nicola [13] focus on the optimization of the flux berries of the line-start synchronous reluctance motor by using the electromagnetic design procedure. They have used the automatic optimization algorithm for designing the arc shaped and trapezoidal shaped flux barriers. After designing those models, to obtain the performance results, Finite Element Method was used. In addition, permanent magnet assisted motor design was also developed and analysed. This study concludes with the revision of the design procedure and the arc shaped rotor design was validated with the better performance in terms of efficiency and magnetic saliency.

Emeka s. obe [14] describe the performance of the line-start synchronous reluctance motor with the study of motor. In this study, the rotor saliency was considered as a key point. The study was undertaken with the reference of induction motor. The developed model of the line-start synchronous motor is having the same cage as an induction motor with the aluminium bars inside it. The method used to perform this analysis is finite element analysis and the results were derived in terms of efficiency and power factor. The machine used in this study is having 2231 W rated output power, rated speed of 1500 rpm, 398 V. Also, the model was tested with the prototype machine. At the end, it concludes that the line-start synchronous motor counterpart the induction motor in terms of power factor and efficiency.

Daniel and Mathias [15] focus on the starting of the line-start synchronous reluctance motor, this study shows the optimization of the line-start synchronous reluctance motor with two diverse types of rotors. This study includes the study of 20kW motor, with 4-pole and 50Hz configuration and tested the rotors by filing them with the aluminium with the finite element analysis. It is concluded with the better start-up of the motor and in order to the performance analysis the line-start motor outperform the same size

of the induction motor and the variation in the amount of aluminium filled in the flux barriers does not affect the performance of the motor.

Damian, Mykhaylo and Bogomir [16] used the geometry based equation for designing the rotor of line-start synchronous reluctance motor. The aim of this study is the online starting performance of the machine. The designed model is having the rated voltage of 210V and 1500 rpm. And to test the performance of designed model the steady state and the transient analysis was performed with the help of finite element method. This study concludes with the different material testing in the start-up of the motor and the torque characteristics were analysed and the model was tested with the different mechanical loading condition conclude with the better torque density.

Q. smit, A. Sorgdrager and R. wang [17] focus on the design and the optimization of the line-start synchronous reluctance motor. The standard 2.2kW, 525V, 4-pole 3 phase induction motor was selected as a benchmark model. For the designing process the stator part of the model kept same as reference motor. The flux barriers were optimized by assuming the magnetic field contained by the stator and it developed three unique designs of the synchronous reluctance motor. The cage bars kept same as a referenced induction motor. This study concluded with the finite element analysis to check the performance of operation and it was concluded that the line-start synchronous reluctance motor can replace the induction motor in terms of the cheaper alternative of the induction motor with the better efficiency. And also, better for the economical production as induction motor.

2.4 Line-start permanent magnet synchronous reluctance motor

In this part of the review there are not much literature available for the permanent magnet with the line-start capability. So, the papers used are more related to the permanent magnet assisted synchronous reluctance motor. So, Wanzhen, Gaangqiang, Li and Yan [18] describe the rotor design optimization of the permanent magnet assisted synchronous reluctance motor with the ferrite magnets. In this study the motor was designed with the optimization of the flux barriers by deriving the distance between the adjacent poles, ratio of flux barrier width to iron sheet width. And the designed model was analysed for its torque nature with the help of finite element method. This paper contributes in the optimization of the flux barriers and the techniques for the accommodation of the permanent magnet on the rotor.

Stjepan, Damir and Marinko [19] made the comprehensive approach for designing the permanent magnet assisted synchronous reluctance motor. Also, prototype model is designed for the 100 kW and analysed using finite element method. But, there is not much novel about analysis from this study.

Robert, Hamid [20] describe the design and comparison of an optimized permanent magnet assisted synchronous reluctance motor. This study focus on the 7.5HP, 4-pole, 460V electrical machine. Before developing the machine the reference induction motor was analysed and studied for the improvement of

L_D and L_Q using the flux linkage computation. The method used for performance analysis is finite element method in 2D software. This study gives the conclusion that, the output torque of the motor is high with the use of same stator as an induction motor. Due to less weight the motor give very fast response to the dynamic transient and the motor has made improvement in terms of efficiency compared to induction motor.

Mohamed, peter, Essam [21] presents the evolution of synchronous reluctance motor with and without permanent magnets and performance analysis. In this study also, one design was taken as a reference design. The machine was developed for 4-pole, 36 slots for study. With the help of magnetostatic analysis, the study of flux paths and density on the different areas of the geometry is carried out. With the help of that analysis, q-axis and d-axis representation was carried out and the method used for the performance analysis is finite element method software. In the result of this study it has been concluded that the notable increment has been done in the power factor and efficiency of the machine.

Dong-Hoon, Yunsang, Ju and Chang sung [22] focus on the study of optimal design of the permanent magnet assisted synchronous motor loading ratio for getting the ultra-premium efficiency. In this study, first the induction motor was selected as a representative industrial method. This study presents that the stator and the rotor of this motor has been developed with the response surface method. And tested with the finite element analysis. The motor has the rated output power of 2.2kW, reted speed of 1800 rpm for this study. The performance results derived using the software simulation as well as prototyping. This study concludes with the ultra-premium efficiency of the designed motor and it can replace the induction motor.

2.5 Gap Statement

From the literature review of the specific design of the synchronous reluctance motor has obtained the area, where the special contribution can be made. From the review, it has been identified that most of the papers are focus on the design of the line start synchronous reluctance motor. And there are few of them which contributes for the load test at different values. Also, there is not much research done in the permanent magnet synchronous reluctance motor with the line-start capability. So, with the benchmark induction motor the study of the parametric optimization can be done and the line-start synchronous reluctance motor can be developed and also with the prediction of the better performance the rotor cage and the permanent magnets can be accommodated in the rotor. So, the new design can be done on the line-start permanent magnet assisted synchronous reluctance motor and the transient and steady state performance analysis in FEM (finite element method) software.

2.6 Contribution

The aim of project is to develop the design of high efficiency synchronous reluctance motor with the better efficiency and power factor. And the design is proposed to be self-starting, with hybrid construction of the rotor with the combination of the induction motor and synchronous reluctance motor using the same type of stator. The analysis is performed in order to get the performance results of the motor design in different loading conditions and to obtain the magnetic circuit operation throughout the machine.

Chapter 3

Design Aspects

3.1 Induction motor as a benchmark model

Fig 6 illustrates the full geometry and winding configuration of the induction motor with the rated output power of 20kW, 4-pole, 50Hz under study, which is considered as a benchmark model of the study. So, basically the induction motor consists of the stator, and the rotor in the cage form with the rotor conductor bars, which is made from the cast aluminium and the shaft of the motor is the non-magnetic shaft.

(a) Induction Motor Geometry

(b) winding configuration of the motor.

Fig 6 Full geometry and winding configuration of the induction motor.

figure 6(b) is the whole 3-phase winding diagram of the induction motor with 36 stator slots. The basic working principal of the motor is electromagnetic induction obtained by the rotor from the stator winding. In this model, the double layer winding is used and the winding type is the whole coiled. Basically, there are two types of the rotor used in the induction motor such as wound type and squirrel cage type but here the cage type of the configuration used in the induction motor. These types of the motors have made very huge contribution for the industrial application. Basically, the synchronous motors rotate at the same speed of the field in the stator. But the induction motor rotates bit slower than the field of stator. That difference of rotational speed and synchronous speed in the percentage ratio of synchronous speed is called the slip of the motor s . The slip can be calculated with the help of formula below.

$$S = \frac{n_s - n_r}{n_s}$$

Where, n_s is stator field speed, n_r is actual rotation speed of the rotor.

The torque of a three-phase induction motor is proportional to the flux per stator pole, rotor current and the power factor of the rotor so, the torque formula of the induction motor can be,

$$T = K_1 E_2 I_2 \cos \phi_2$$

Where, K is the constant, I_2 is the current of rotor at standstill condition, ϕ_2 angle between rotor current and rotor EMF and E_2 is the rotor EMF at stand still condition.

Now, the maximum starting torque of the induction motor can be defined as,

$$T_{st} = K_2 R_2 / (R_2^2 + X_2^2)$$

Where, R_2 is the rotor resistance per phase and X_2 is the rotor reactance at standstill condition. And the equation for the torque under running condition can be,

$$T = (K_1 s E_2^2 R_2) / \sqrt{(R_2^2 + s X_2^2)}$$

$$T = 3/2 \pi N_s (s E_2^2 R_2) / \sqrt{(R_2^2 + s X_2^2)}$$

The speed torque characteristics of the double cage induction motor is given in the figure 7 compared with the inner cage and outer cage.

Fig 7 Torque speed curve of double cage induction motor [23].

3.1.1 Specification of the motor under study

In this part of study, the overall general specifications of the induction motor are given in the table 2. The basic ratings of the machine are 20kW, 50Hz, 4-pole with 1470 rpm. And the operating temperature of the machine is kept 75° C.

The stator of the machine has 36 slots. And the inner diameter is 254 mm and the outer diameter of the machine is 165 mm. the material used in the construction of the core parts of the motor is M19_24G steel. And the rotor conductors are made from cast aluminium.

On the rotor side of the machine, double cage configuration is used with 28 slots. The airgap is kept 0.55 mm. And the shaft diameter is 45mm for this induction motor. After the study of the specification the whole geometry is built for the optimization of the performance results with the different loading condition.

Table 2 Inductor motor specifications under study[15].

General data of machine	
Given output power (kW)	20
Number of poles	4
Given speed (rpm)	1470
Frequency (Hz)	50
Operating temperature (°C)	75
Stray loss (W)	200
Type of load	Fan Load
Winding connection	Wye
Stator data	
Number of stator slots	36
Outer diameter of stator (mm)	254
Inner diameter of stator (mm)	165
Rotor data	
Number of rotor slots	28
Airgap (mm)	0.55
Shaft diameter (mm)	45

3.1.2 Stator

The stator of the induction motor is made from the laminated iron. And the stator slots are filled with the copper winding. But, in this thesis the focus is not on the design of the stator but, this part of the report shows the stator specification and the detailed specification of the stator is illustrated in the appendix a. and the stator geometry is given in the figure 8. The winding configuration are remained same as fig 6.

Fig 8 Stator of an induction motor.

3.1.2.1 Stator slots

The design of the stator slot is very important while designing the electrical machine. The figure 9 show the slot design of the stator used in the benchmark model of the induction motor and the slot dimensions are illustrated in the table 3.

Fig 9 Definition of stator slots

Table 3 Stator slots dimensions

Bs1	7.16mm
Bs2	10.6mm
Rs	0.2mm

3.1.3 Rotor

Here In this project rotor of the induction motor is having dual cage configuration the detailed dimensions of the rotor are illustrated in the appendix a. Rotor of the induction of the motor is also made from the laminated iron M19_24G. the whole geometry of the motor is illustrated below in the figure 10.

Fig 10 Rotor of an induction motor.

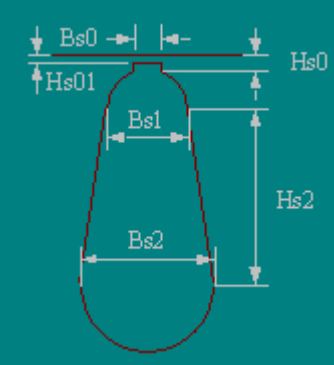

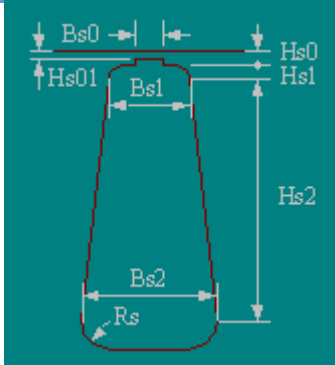

Here, the double cage is used in the induction motor. Because there are several advantages of using double cage configuration such as, they are cheaper and robust in construction, it is having high efficiency and power factor, they are basically explosion proof. Also, it has higher starting torque and lower starting current.

3.1.3.1 Rotor slots

In this rotor, the dual cage configuration is used so, there are two different slots are used. As, there are several advantages of using the double cage rotor. One of them is, double cage rotor reduces the starting current and the starting torque of the dual cage is higher. So, better torque density can be obtained with the use of the double cage rotor.

The dimension of the slots is illustrated below in the table 4.

Table 4 Dual cage rotor slots dimension.

 (a) Inner slots		 (b) Outer slots	
Hs0	0.35 mm	Hs0	1.5 mm
Hs01	0.35 mm	Hs1	1 mm
Hs2	0 mm	Hs2	18 mm

Bs1	7.5 mm	Bs1	6.7 mm
Bs2	7.5 mm	Bs2	2 mm
		Rs	1 mm

With the help of study this bench mark model the design procedure moved on the additional design of the proposed models. In the next part the design of the proposed models are illustrated. So, the induction motor was designed in Maxwell 2D for the parametric optimization.

3.2 Design of line start synchronous reluctance motor

Basically, synchronous reluctance motor has the same number of slots on its stator and rotor. So, with the help of flux line analysis the flux barriers are designed. These barriers can direct the magnetic flux so, the axis which is between two flux barriers can be identified as direct-axis of the motor.

Fig 11 study of flux line travelling path on solid core rotor.

The synchronous reluctance motor is having generally 4 and 6 poles. Rotor of the motor is made from the laminated iron so, it has not any current conducting part. So, the rotor losses can be minimal in comparison with induction motor. So, with the help of this path orientation the approximation on tracing the flux barriers can be made.

But, these motors once start at synchronous speed it is operating on sinusoidal voltage. So, the variable frequency drive can be required for the speed control of the motor.

On the other side, for the constant speed application the new idea is introduced to add cage in the rotor part, so it can achieve the line-start capability. So, the designing method of the line-start synchronous motor is described in detail in further.

3.2.1 Optimization of rotor design with two distinct aspects

For designing the rotor, the basic step is to study the distribution of the flux line on the core. So, the flux representation was checked and the approximate analysis was carried out for the design of the flux barriers on the rotor.

In the second step of the design, the approximation of the placement of the flux barriers was made as the q-axis flux is blocked by the barriers and the d-axis flux should not much affected. In addition, the optimization of the width of the flux barriers is very important. The whole phenomenon of the width is decided from the approximation of the flux line representation. Basically, it depends on the air/ iron ratio. And the performance of the synchronous reluctance motor depends on the saliency ratio which is defined as,

$$\xi = \frac{L_d}{L_q}$$

Where, L_d inductance along direct axis, L_q inductance along quadrature axis.

The reluctance torque is generally affect the ferromagnetic part placed in the magnetic field, which force the object to line up with the magnetic field. The external magnetic field produces the magnetic field in the object so, the torque is produced. Because of this generated torque, the object is twisting around the line with the magnetic field this torque is also called saliency torque. Reluctance motor operation relay on the reluctance torque. The equation of the reluctance torque can be given by,

$$T_{rel} = k \left(\frac{V}{f} \right)^2 * \sin(2\delta_{rel})$$

Where, T_{rel} = Average reluctance torque, V is the applied voltage, δ_{rel} is the electrical degrees and k is the motor constant.

The barriers are designed with two different shapes such as, hyperbolic curve shape and hyperbolic line shape. The design dimensions of these two assorted designs are illustrated below. The stator of the line-start synchronous reluctance motor is kept same as much as possible in terms of parameters. So, the only change is done with the rotor of the motor.

As, the synchronous motors are not having the line-start capability. So, the aluminium cage is inserted in the rotor with the help of 2D software. So, the overall parameters and definition of the motor is given in table 5.

Table 5 Line-start synchronous reluctance motor.

Motor parameters	Data
Outer diameter of the rotor (mm)	164.45
Diameter of the shaft (mm)	45
Number of barriers, k	4
Bottom radius of the barriers R_b (mm)	29.35
Bottom thickness of the barriers B_o (mm)	9.6
Bottom yoke thickness, Y_o (mm)	9.825
Thickness of bridge H (mm)	0.5
Aluminium outer radius, r_{out}	78.25
Aluminium inner radius r_{in}	70
Shape of barriers	Hyperbolic Curve, Hyperbolic Line

(a) Hyperbolic-Curve rotor barriers.

(b) Hyperbolic-line rotor barriers.

Fig 12 Line-start synchronous-reluctance motor.

For getting more better performance these motor models are modified by inserting the magnets in the flux barriers. So, the modification and the design optimization of the motors is described in the next part of the report.

3.3 Design of line-start permanent magnet synchronous reluctance motor.

Basically, there is not much research done on this kind of the motor. So, the previous papers on permanent magnet synchronous reluctance motor are studied for finding the better way to insert the magnets in the flux barriers. So, basically these magnets saturate the rotor bridges, which can be helpful to increase the torque density and the power factor of the motor. Also, the reluctance torque of the motor increases.

3.3.1 Permanent magnet

The magnets selected for these motor design is NdFe30 because these magnet material is majorly used for the permanent magnet motors. These types of magnets are commonly available. And the different properties of the magnet used in this motor is illustrated below, in the table 6. And table 7 shows the size of the permanent magnets.

Table 6 properties of the permanent magnet.

Magnet Properties	
Magnet Type	NdFe35
Relative Permeability	1.0997785406
Bulk Conductivity	625000 siemens/m
Magnet Coercivity	-890000 A/m
Mass density	7400 kg/m ³

Table 7 dimensions of the Magnets.

Motor Type	NdFe35 Magnet size (mm)		
	Mag 1 (Barrier 1)	Mag 2 (Barrier 2)	Mag 3 (Barrier 3)
Hyperbolic curve (LSPMSynRM)	9.6mm	7.2mm	6.2mm
Hyperbolic line (LSPMSynRM)	9.6mm	7.2mm	6.2mm

So, after the orientation of the magnets in the rotor the final design of the motor looks like fig 13. Which is having the same stator as the benchmark model and the rotor is having the permanent magnet and the aluminium cage.

(a) Hyperbolic-Curve rotor with magnets.

(b) Hyperbolic-line rotor with magnets.

Fig 13 final design of the line-start permanent magnet synchronous reluctance motor

Finally, all the designed models were simulated for testing the performance in different loading condition. So, the simulation and parameters and testing are illustrated in the next chapter of the report and furthermore, all the obtained results are described and compared with the results of the reference induction model.

Chapter 4

Simulation and Parameters

4.1 Simulation Method

In this part of the chapter the method used for the analysis of the designs and the different types of analysis are described in detail. In the basic steps of the research, the Ansys Maxwell RMXprt Which is one of the algorithm based program. It is used to build benchmark model for the parametric optimization of the induction motor. It can calculate the performance parameters in the very brief period. But, these results are not more reliable so the machine was tested with the finite element analysis method. first of all the induction motor was set for the no load analysis. The simulation time was kept 0.6s with the step time of 0.002s. And the motoin was assign to the model. The meshes are provided for the different components and the induction machine was validated with the validation check feature of the software. Once the machine has been validated for its construction and parameters, it was simulated. Fig 14 shows the initial modelling of an induction motor with the help of RMXprt.

Fig 14, Induction motor modelled in RMXprt.

For the better computation of the performance results all the models are designed in Maxwell 2D software package. This software consists of different designing tools available to design different shapes and components. Basically, this research is carried out using Maxwell 2D because 3D modelling is more time-consuming process. Also, it takes long time to simulate the model because of the large numbers of the simulation elements. In this part of the simulation there are three sub parts included. These three sub parts of the chapter shows the detailed analysis such as magneto static analysis and some of the brief instruction on the steady state analysis and transient analysis because these points are illustrated in detail in the next chapter including all the results with different loading condition. All the results of the steady state and transient analysis are computed with the help of finite element analysis.

4.2 Magnetostatic analysis

Basically, FEA works with the help of meshing process. Because of that, mesh application also matters to the accuracy of the results. The performance results of machine were derived from the simulation for all designed models. And also with the help of magnetic analysis method, the magnetic circuit of the rotating machine was obtained. These machines were tested for the flux density, flux linkage, and the air-gap flux density distribution with the help of magnetic analysis.

Magnetostatic analysis is basically used for getting the quantities such as, magnetic field because of the currents and permanent magnets in the machine. This analysis can be carried out for different applications such as, motors and generators, relays, sensors and solenoids. Here, this analysis is used for motors.

The magnetostatic analysis is performed for no-load and full-load conditions. In the no-load condition there is not any mechanical load is applied to the motor and it is rotating freely. And in the full load condition the full load value was calculated for the motor and the value of full load was applied from the option of mechanical load application in the motion setup of the project.

For all the models, different flux density for no-load and full-load condition is illustrated in the fig 15 and figure 16 respectively. The flux lines representation is illustrated in fig 17 and 18 for the same two loading conditions.

The other results are obtained for the vector representation of the flux distribution at the different part of the rotating machine is shown in fig 19 and 20 with no-load and full load operating condition with the appropriate legends. All the results are illustrated in for the rotational motion of the machines.

Fig 15 Flux density of all five models at No-Load.

Fig 16 Flux density of all five models at Full-Load.

From the figures, it was noticed that the magnetic flux density is high in the core part of the motors such as rotor and stator. Here in the figure the orange and green areas represent the higher flux density and blue areas are stand for low flux density in the machines.

With the help of magnetic flux lines representation, the magnetic circuits can be retrieved in the machine. Here, in figure below the flux lines representation shows red colored line for the higher flux passing and blue and green lines shows the less flux density on the flux travelling path. Also, from this representation how the flux can be locked with the rotor and stator can be examined. Again, here there is not much difference in the flux lines representation for both no-load and full-load condition. In the induction motor, the flux lines passes between rotor slots to stator tooth. And for the hybrid motors it is

passing around the flux barriers. In the LSPMSRM (hyperbolic curve and line) flux lines are passing through the magnets and around the flux barriers.

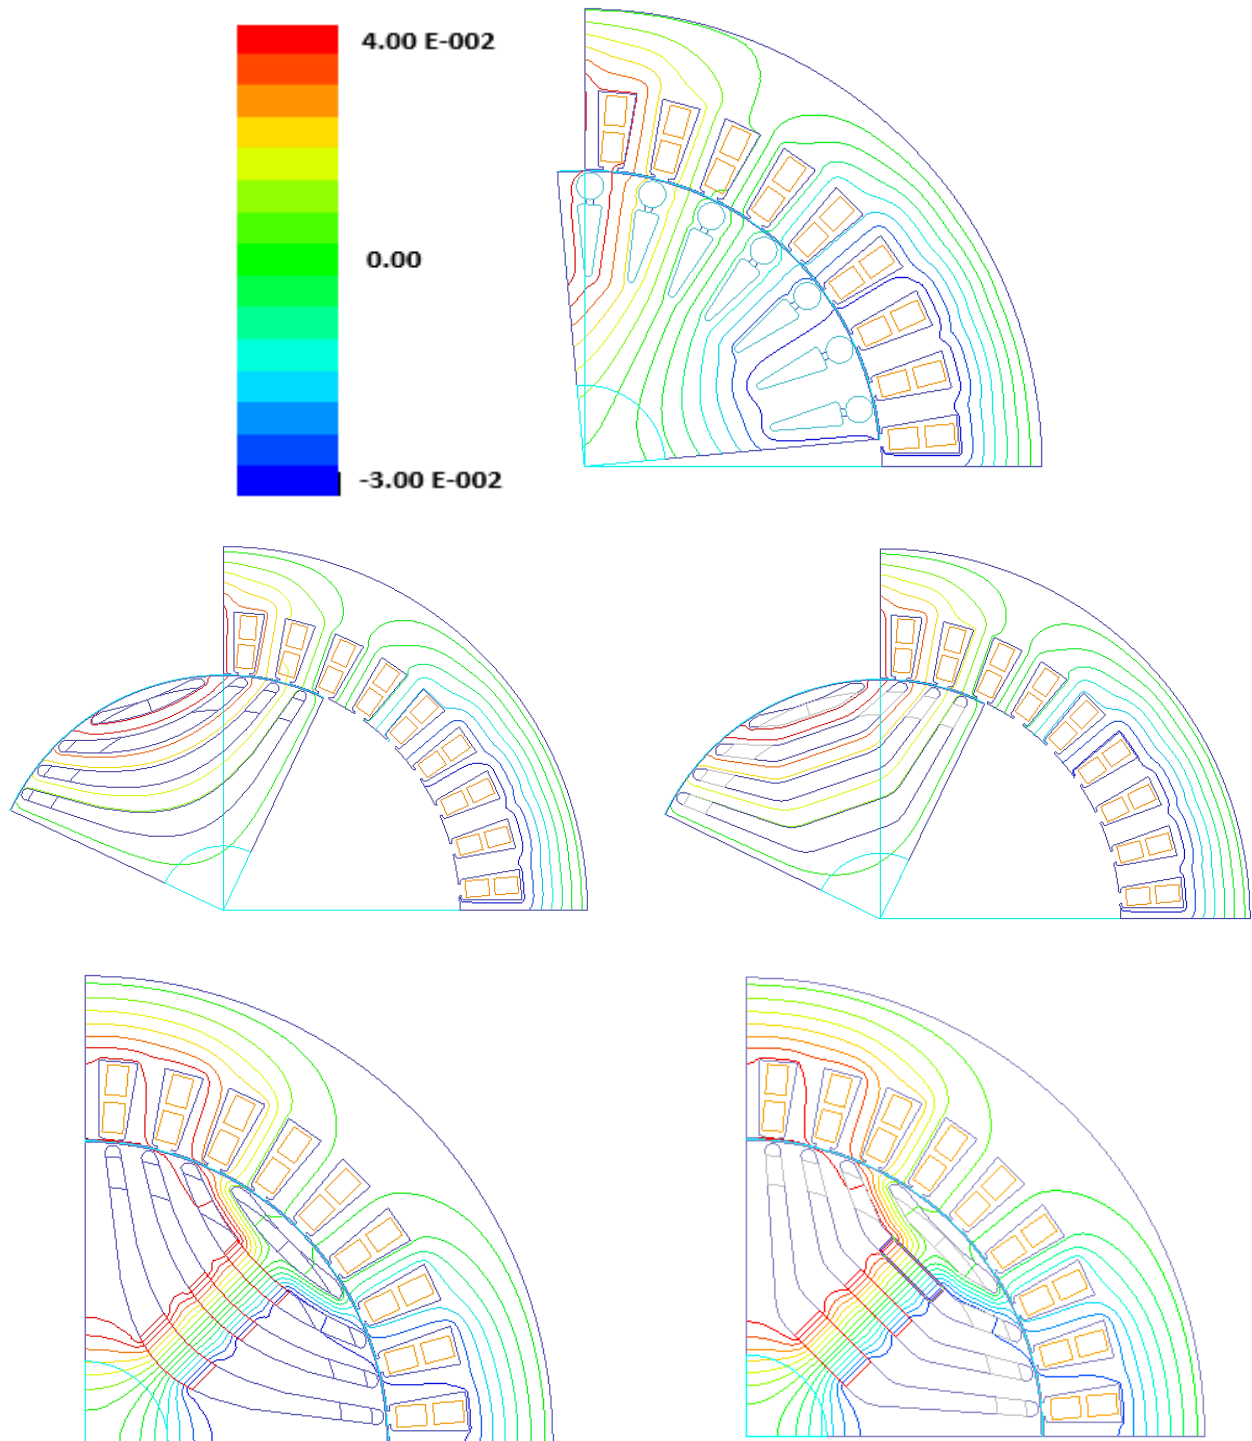

Fig 17 Flux lines representation at no load (Wb/m).

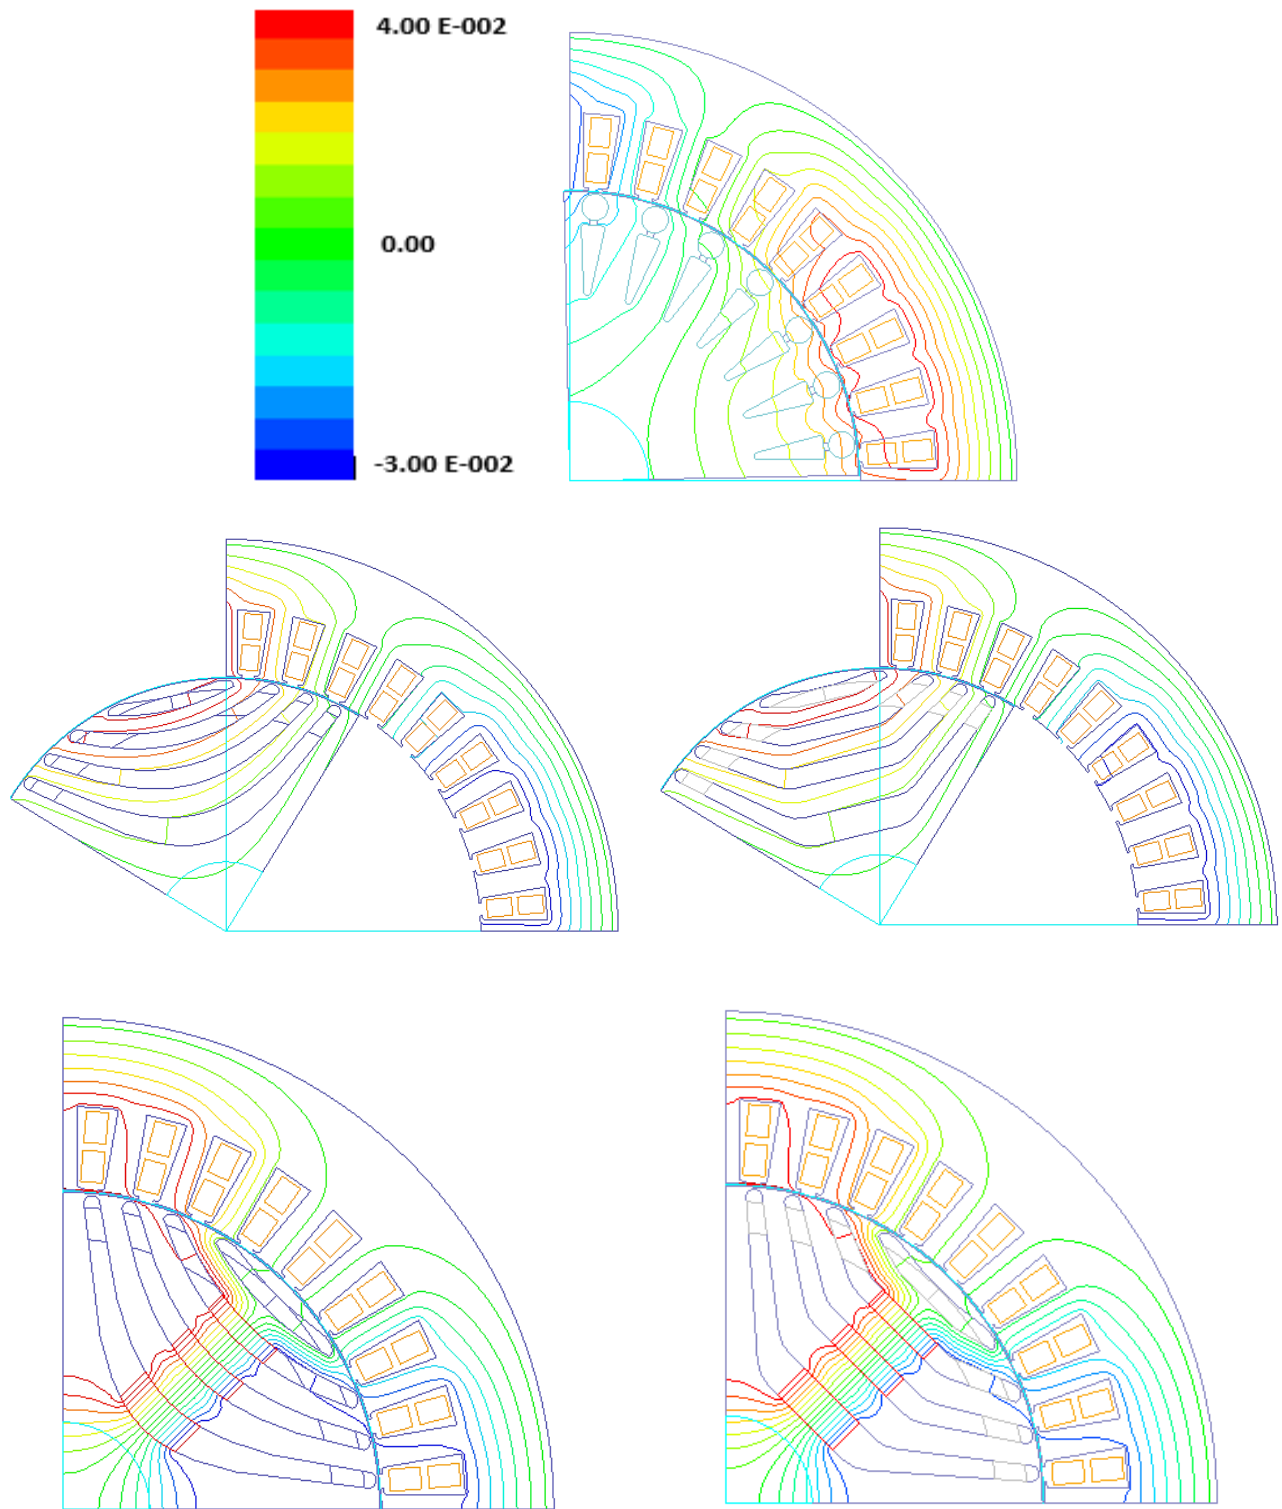

Fig 18 flux lines representation at full load (Wb/m).

Magnetic flux vector representation is also carried out with the all five designed models and with the help of this plots the flow of the magnetic flux with different intensity can be identified in the different parts of the motors. From the figures it was noticed that the vectors are uniformly distributed on the

every part of the machine but some of the vectors are scattered but this kind of the flux has very negligible effect on the operation.

Fig 19 Magnetic flux vector representation for all five models at No-Load.

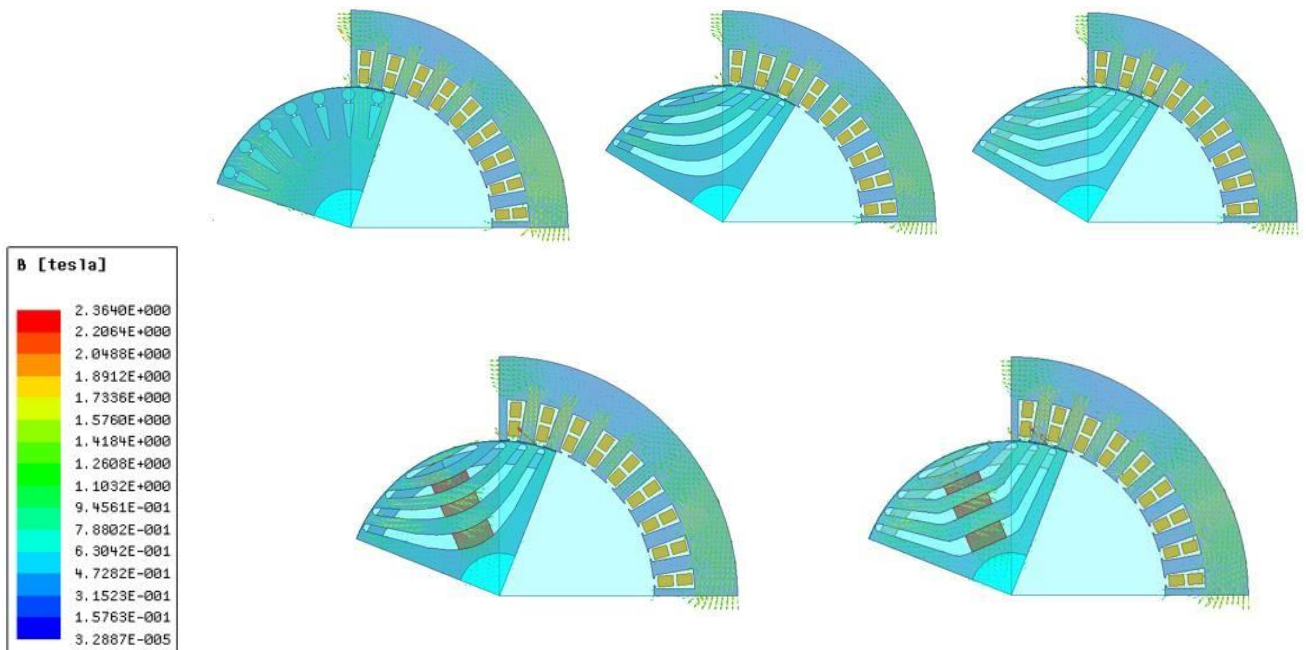

Fig 20 Magnetic flux vector representation for all five models at full-Load.

So, with the help of magneto static analysis of all the models the magnetic circuit and the flux density on the different areas of the motors are obtained. Also, the flux locking and the travel path of the flux has been identified on the designed models.

4.2.1 Air Gap Flux Density

In this part of the chapter the flux density in the airgap of the machine is illustrated. So, the amount of flux density in the airgap can be measured with the help of this analysis. From this analysis, the idea of the airgap length can be derived and tested for, whether it is ok or it needs any modification. It also gives the idea about the travelling path of the flux from the airgap.

The results below shows the flux density passing through the airgap in the one segment of the machine for all designed models for both no load and full load condition when machine is rotating. Here, the air gap flux density is derived with the help of arc formation in the air gap and then the flux density at the specific arc has been measured and illustrated in the plots further.

From the fig 21 it has been noticed that in the induction motor the air gap flux density at the stator slot opening is less and the air gap flux density is increasing near the stator tooth. In the fig 21 the segment of the induction motor shows the air gap flux density.

Fig 21 Air gap flux density in the induction motor.

Furthermore, the airgap flux density is obtained for other four proposed design which is illustrated in the fig 22. From the results it is noticed that, the air gap flux density at no load is less than the air gap flux density at full load for all the models.

Airgap flux density

(f) LSPMSynRM (Hyperbolic Curve)

(g) LSPMSynRM (Hyperbolic Line)

(h) LSPMSynRM (Hyperbolic Line)

Fig 22 Airgap flux density at No-load and Full load.

4.2.2 Magnetic Flux Linkage

The magnetic flux linkage plots shows how much flux travelling through the coils and plots for the flux linkage for all the motors in the no load condition and the full load condition are illustrated further.

Basically the induced EMF and the derivative of the flux linkage is proportional to each other so, the equation for that is illustrated below,

$$e = N \frac{d\phi}{dt}$$

Where, e is the induced EMF, N= number of turns of coils and ϕ is the flux linkage.

Here, fig 23 shows the magnetic flux linkage of all the coils at no load. When the saturation takes place in the machine the flux linkage wave form get scatteded otherwise the waveforms are in the sinusoidal shape. The reason of being scattered can be the saturation in the core. In the plot, the different phase ha different color notations. So, when the alternating flux frequency increase as a result, the losses of the machine get increases.

(a) LSSynRM (Hyperbolic Curve)

(b) LSSynRM (Hyperbolic line)

(c) LSPMSynRM (Hyperbolic Curve)

(d) LSPMSynRM (Hyperbolic Line)

Fig 23 Flux Linkage at No-Load.

From the figures above, it can be seen that there is not much difference in both of the line-start synchronous reluctance motor and line-start permanent magnet synchronous reluctance motor. All the waveform for the no load condition are finely sinusoidal. All the flux linkage plots are derived with respect to time in this simulation. It shows the flux linkage during whole operation of the machine.

Here, fig 24 shows the flux linkage plots for the full load condition for the line-start synchronous reluctance motor as well as line start permanent magnet synchronous reluctance motor.

(a) LSSynRM (Hyperbolic curve)

(b) LSSynRM (Hyperbolic line)

(c) LSPMSynRM (Hyperbolic curve)

(d) LSPMSynRM (Hyperbolic line)

Fig 24 Flux linkage at Full-Load.

From the figures, it is noted that the flux linkage for all the designed machines are sinusoidal. There is a minor fluctuations noted at the start-up of the motor. But the starting response of the flux linkage does not affect the performance of the motor. These full load flux linkage of the machine is almost similar to the no-load flux linkage of the machines. But, with the comparison of the flux linkage for no-load and full load condition, there is a phase difference in the waveform in both loading condition. This phase difference can be the resultant of the winding inductance of the machine.

4.3 Summary of Magnetostatic analysis

In this step of the research the magnetostatic analysis is carried out with all the machines. The magnetic circuit of the machine is understood. With the help of field plots the magnetic flux density is measured and the travelling path of the flux is derived.

Also, the airgap flux density for all the machine is obtained for both no-load and full load condition. The flux linkage relationship with the EMF has been studied and it is noticed that the flux linkage plots are finely sinusoidal for both no-load and full-load condition.

4.4 Steady-state analysis

When the electrical machine obtains the original state, this state is called the steady state stability. So, when the motor gains the synchronous speed the winding currents and the torque can be back to the steady state position. So, in the steady state analysis the quantities such as winding currents, phase voltages or the torque plots can be included. So, the steady state performance of the models is illustrated below in the open circuit test section.

4.4.1 Open-Circuit analysis or No-load test

Basically, the no load test on an induction motor is used to obtain the data of the currents and no-load losses. While performing this test, three phase voltage is applied to the stator windings and in the no load condition of the motor, there is not any mechanical load connected with the rotor. So, the motor can be able to rotate freely without any blocking. At no load condition, the designed models are tested for different parameters such as, speed, torque, input power, output power, winding currents and losses and power factor. And from the obtained power the efficiency is calculated for the no load condition.

At last all the results for the no-load test are compared with the reference model (induction motor) and the conclusion will be made in the next part of the report.

4.5 Transient analysis

When the electrical machine is operating under the loading condition and when it is not in the steady state condition is called the transient operation of the machine. In the transient analysis, the designed motors are simulated with the different loading condition such as, half-load, Full-load and more than full load. So, same as the steady-state analysis all the parameters of operation such as, speed, torque, input power, output power, losses, power factor and efficiency under the different loading condition. But, results for the full load condition is only illustrated in the next chapter of the report. Results for the half-load and more than full load are illustrated in the appendix B at the end of the report.

4.5.1 Full Load Testing

in this part of the simulation the motion model was modified with the full load mechanical load application. Before testing the machines, the full load for the machine was calculated theoretically and applied on the motor. The results for all the models are derived and captured in the form of image and described in the next chapter in detail. All the models of the project are tested for the same parameters as steady state analysis. In the next chapter of the thesis, all the results for the no load and full load condition are compared and tested for their performance.

The summary of the models considered for the simulation is given below in the fig 25.

(a) Induction motor

(b) LSSynRM (Hyp. Curve)

(a) LSSynRM (Hyp. Line)

(e) LSPMSynRM (Hyp. Line)

Fig 25 Models considered for the simulation.

Chapter 5

Results and Discussion

5.1 Start-up of the Motor

In this part of the chapter, the focus is on the starting of the motor and the time to reach the full rated speed is examined. For the starting analysis of the motor the plot for the speed Vs. Time is considered. The simulation was carried out for 600ms and the step time was set to 2ms. While testing the motor for the starting performance it is tested for two different loading condition such as no-load and full load. The results for no-load and full-load are illustrated in fig 26 and fig 27 respectively.

(a) Induction motor at No-load

From the graph above, it can be clearly observed that the induction motor is getting the speed of 1470rpm at 250ms and operated with minor fluctuations with an average speed of 1450.93rpm which is expected result and it matches the outcome of the previous paper.

(b) LSSynRM at No-load (Hyperbolic curve)

For line-start synchronous reluctance motor, it can be observed that the startup of the motor is almost same as compared to the induction motor but, this motor got synchronized at 400ms and then it is operating on the constant speed of the 1500rpm. But, from the comparison with an induction motor it is noticed that the line start synchronous reluctance motor with hyperbolic curve shaped barriers in rotor is taking more time to get constant speed.

(c) LSSynRM at No-load (Hyperbolic line)

The line-start synchronous reluctance motor is also getting speed of 1500rpm at 400ms, which is almost same time taken by the motor with hyperbolic curve rotor configuration. In addition to that, the startup of both the motors remained same compared to the induction motor. Because the induction motor is having the cage type rotor construction. And the line-start synchronous reluctance motor is also having the Aluminum cage in the rotor.

(d) LSPMSynRM at No-load (Hyperbolic Curve)

Now, in the line-start permanent magnet synchronous reluctance motor with both of the hyperbolic curve and hyperbolic line rotor configuration the permanent magnets are used and accommodated in the air barriers. Because of this magnets, the rotor is also having its own magnetic field. Also, these models are less with the cage in the rotor. So, because of the magnets the motors are taking less time for the synchronization process and synchronized and rotate on 1500rpm in 300ms which is 100ms quicker than the models without magnets. So, these models with magnets are better startup compared to models without magnets.

(e) LSPMSynRM at No-load (Hyperbolic Line)

Fig 26 speed Vs. Time at No-load (0Nm).

From the speed plots, it is concluded that, because of the aluminum cage the synchronous reluctance motor start as an induction motor. There are certain transients during the start-up of the motor but at the time of 400ms the line start synchronous motor trying to achieve the synchronous speed of 1500rpm.

Also, looking at the line-start permanent magnet synchronous reluctance motor, it is trying to get the synchronous speed earlier compared to the models without magnets. On the other hand, the plots for the full load operation, the plots for speed vs. Time is illustrated in the fig 27 below.

(a) Induction motor at full load.

(b) LSSynRM at full load (hyperbolic curve)

(c) LSSynRM at full load (hyperbolic line)

(d) LSPMSynRM at full load (Hyperbolic curve)

(e) LSPMSynRM at full load (Hyperbolic line)

Fig 27 Speed Vs Time at full load.

While simulating the models at full load the mechanical load of 127.38Nm is applied to the motor. And the plots for the speed are obtained. So, from the plots at full load models of LSPMSynRM and LSSynRM are getting speed of 1500rpm.

At full load operation, the motors are taking more time for getting synchronous speed compared to the no-load plots. Line-start synchronous reluctance motor is taking 400ms for reaching to the synchronous speed and the line-start permanent magnet synchronous reluctance models are also taking 350ms to achieve the synchronous speed. So, from the observation it can be said that the line start synchronous reluctance motor is having better performance compared to induction motor and the line-start permanent magnet synchronous reluctance motors are better at operation compared to models without magnets and the reference induction motor.

And, from these results it can be said that, because of the arrangement of the aluminum cage with the synchronous reluctance motor and permanent magnet synchronous reluctance motor, models are getting almost same starting characteristics as the reference induction motor. So, these kinds of motor can replace induction motor in terms of the starting characteristic.

5.2 Winding currents

In this part of the chapter the focus is on nature of the winding currents of the motors. Here, all five models are tested for the nature of winding current. The nature of the winding current matters a lot in the performance of the motor. Because of the same balanced flow of the winding currents for all the models, the plots are illustrated for the different motors below in the fig 28.

(a) Winding currents for Induction motor.

(b) Winding currents for LSSynRM (Hyperbolic Curve)

(c) Winding currents for LSSynRM (Hyperbolic Line)

(d) Winding currents for LSPMSynRM (Hyperbolic curve)

(e) Winding currents for LSPMSynRM (Hyperbolic Line)

Fig 28 Nature of winding currents.

For the better and smooth operation, the winding currents should be finely sinusoidal or balanced in terms of phase shift and magnitude.

From the plots of the winding currents, for all the designed models the winding current waveforms are having almost balance condition in terms of the magnitude and phase shift. The reason for having unbalance winding currents can be the reactance of the three phases is not same as a result it causes the unbalancing in the current, which may be effect the efficiency and the working performance of the machine. If the motor works on the unbalanced winding current. This cause the degradation of the rotor and the winding of the stator. That unbalancing of the motor draw more losses and the heating of the machine.

Also, if the winding currents are more fluctuating, it causes unbalancing in the torque and the unbalancing of the torque can cause the vibration during the operation, which leads to the destruction of the machine or the system connected to it. To reduce this kind of unbalancing, the phase reactance of the motor should be changed and the motor winding should be replaced. But, here the winding currents for all the models are in balanced condition in terms of the magnitude and the phase shift. So, these machines are having the better performance.

Furthermore, the torque produced by the motor is tested with the help of Torque Vs Time plots. It is described in detail in the next part of the chapter.

5.3 Torque Produced by Machine

The torque of the machine is also called the turning force through the radius of the machine. These plots were obtained to check the starting torque of the machine and the torque produced by the machine during the no-load and full load operation at the synchronous speed. So, the plots for Torque vs. Time is illustrated below in the fig 29 and fig 30 for no-load and full load respectively. At no-load condition the torque in the induction motor is 0Nm. And from the plot (a), when the induction motor reach at its full speed, the torque is fluctuating around zero.

(a) No-load torque of Induction motor.

(b) No-load torque of LSSynRM (Hyperbolic curve)

(c) No-load torque of LSSynRM (Hyperbolic Line)

(d) No-load torque of LSPMSynRM (Hyperbolic curve)

(e) No-load torque of LSPMSynRM (Hyperbolic Line)

Fig 29 Torque Vs Time at No-load.

From the plots (b) and (c) of fig 29 the average torque becomes zero once the motor start running on synchronous speed. Also, the line-start synchronous reluctance motor producing the high torque for getting the motion and once it reached to 1500rpm, the torque becomes zero. The same reason is also applied for the line-start permanent magnet synchronous reluctance motor and plots (d) and (e) shows the

torque vs time graph for LSPMSynRM.

Because of the high starting torque of the designed models, these machines can be used for the industrial application such as cranes, rolling mills and also it can be used to run the large conveyors.

Also, the nature of the torque is tested for full load condition. So, during this simulation the full-load value of 127.38Nm was applied in the mechanical load consideration and the machines were tested for the same time frame.

The full load results of the analysis are illustrated below in the fig 30.

(a) Full-load torque of Induction motor.

(b) Full-load torque of LSSynRM (Hyperbolic curve)

(c) Full-load torque of LSSynRM (Hyperbolic Line)

(d) Full-load torque of LSPMSynRM (Hyperbolic curve)

(e) Full-load torque of LSPMSynRM (Hyperbolic Line)

Fig 30 Torque Vs Time at Full load.

Basically, the full load torque results show that the torque density of the line start synchronous reluctance motor and the line start permanent magnet synchronous reluctance motor is high compared to the induction motor. Torque density for the LSSynRM and LSPMSynRM for both hyperbolic curve and hyperbolic line configuration is noticed to be 129.38Nm which is almost same compared to the induction motor. So, these motors assumed to be more suitable for the industrial application.

5.4 Loss Analysis of the Machine

In this part of the chapter the focus is on the core loss, hysteresis loss and eddy current losses. So, the machines were tested for both no-load and full load condition. The plots of the losses are represented in distinct colors. Generally, the hysteresis losses in the machine produce because of the hysteresis effect of the material used in the machine and the eddy currents losses are produced because of the induced currents in the steel. The eddy current losses of the machine can be the reason of heating of the machine. Basically, in the induction motor the losses are high because of more current conducting material on the rotor. And, by looking at the construction of the line-start synchronous reluctance machine the mass of the rotor has been reduced so, the material consumption in the rotor of the machine is reduced. So, it directly affects the losses of the machine. So, the losses in the induction motor is high compared to the line-start synchronous reluctance motor and line-start permanent magnet synchronous reluctance motor. The results for losses are illustrated in the figure 31 for the no load condition.

(a) No-load losses of an induction motor.

(b) No-load losses of LSSynRM (Hyperbolic Curve)

(c) No-load losses of LSSynRM (Hyperbolic Line)

(d) No-load losses of LSPMSynRM (Hyperbolic Curve)

(e) No-load losses of LSPMSynRM (Hyperbolic Line)

Fig 31 Losses in the Machine at No-load.

From the plots of losses at no-load, it can be observed that the induction motor is having more loss of 158W compared to the line start synchronous reluctance motor and line start permanent magnet synchronous reluctance motor. Also, it is noticed that the losses are reduced as the evaluation of the new designs without magnets and with magnets compared to an induction motor.

After the no-load analysis, the full load analysis is carried out for obtaining the losses of the machines at full-load condition, which is illustrated below in the fig 32. So, from both the figures it can be seen that the losses in the induction motor is high and it is reduced as the new models developed.

(a) Full load losses of an induction motor

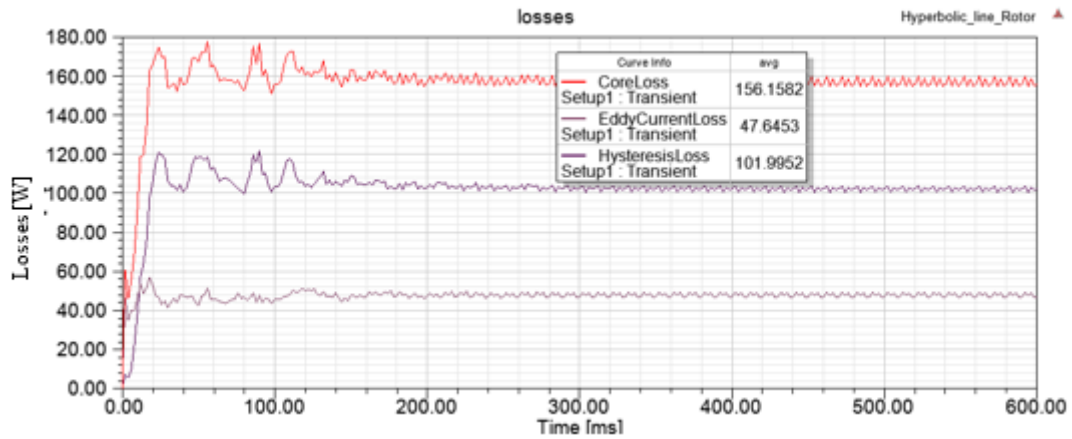

(b) Full load losses of LSSynRM (Hyperbolic curve)

(c) Full load losses of LSSynRM (Hyperbolic line)

(d) Full load losses of LSPMSynRM (Hyperbolic curve)

(e) Full load losses of LSPMSynRM (Hyperbolic Line)

Fig 32 losses in the machines at full-load.

From the full load analysis of the machine it is clearly noticed that the losses in the induction motor is relatively high as 161W compared to the line-start synchronous reluctance motor and line-start permanent magnet synchronous reluctance motor. The overall losses of the induction machine are nearly 161W. And the losses in the developed machines are noted to be 5 to 8% less so, the reduction of losses contributes for the better efficiency of the machines. So, here the new developed models of the motor counterparts the induction motor. Also, the reduction of the losses results in the better efficiency.

5.5 Input and Output Power of the Machine

Here in this part of the chapter the input power and the output power of the machine are measured for both no load and full load condition. Fig 33 shows the combined graph of the input power and the output power varying with the time.

(a) Input power and output power of the induction motor.

(b) Input power and output power of the LSSynRM (Hyperbolic curve)

(c) Input power and output power of LSSynRM (Hyperbolic line)

(d) Input power and output power of LSPMSynRM (Hyperbolic curve)

(e) input power and output power of LSPMSynRM (Hyperbolic line)

Fig 33 input and output power of machines at No-load.

At no load condition, from the plot (a) of figure 33, the input power of the induction motor is noticed to be 17379W but at no load condition the applied load to the machine is 0Nm. So from the formula of the output power the output power should be zero. But, in the plot shows some amount of power which can be considered as a computational error. So, for all rest of the plots the average value of the input power is taken between 400ms to 600ms. In addition to that, the input power for both developed models of LSSynRM and LSPMSynRM is noticed around 4000kW and the output power is considered as 0. Basically, this plots are generated for the calculation of the efficiency. And the efficiency of the machine at no-load should be zero because of the output power of the machine at no load is zero. Which is illustrated in the part 5.7 of the chapter.

Furthermore, the input power and output power are obtained for the full load condition and the plots for the full load is illustrated below in the fig 34.

(a) Input and output power of an induction motor

(b) Input and output power of LSSynRM (Hyperbolic curve)

(c) Input and output power of LSSynRM (Hyperbolic line)

(d) Input and output power of LSPMSynRM (Hyperbolic Curve)

(e) Input and output power of LSPMSynRM
(HyperbolicLine)

Fig 34 input and output power of machines at full load.

Now, at full load the average input power of the induction motor is 25.7kW and the output power for an induction motor at full load is 20.1kW. Also, from the plot (b) and (c) it is observed that the motor is working on the average output power of almost 20kW, when it is operated under the full load condition.

And plots (d) and (e) shows the average output power of line-start permanent magnet synchronous reluctance motor at 20kW. So, from this plots the full load efficiency of the machines is derived.

5.6 Power Factor

Basically, the power factor is also the important factor to consider while designing the electrical machine. Power factor is one of the overlooked and less understood characteristic while designing the electric motor. Power factor can be more important when the operating cost of the machine taken in to account. It is basically measured as the ratio of kW and KVA. The bar chart for the power factor is illustrated below in the fig 35.

The formula used to derive the power factor is given below, and the power factor of all the machines is calculated manually.

$$PF = \text{Mechanical power} / \text{Input Power}.$$

Where, Mechanical power = Input Power – Electrical losses.

Fig 35 power factor of motors at no-load and full load.

From the results, it is noticed that in the no-load condition the power factor for all the machine was around 0.93 and the power factor for the designs with the permanent magnet is 0.94 and at the full load the power factor increased to the 0.97 for the developed new models. So, the higher power factor can also be the reason for the better efficiency of the machine compared to the induction motor.

5.7 Efficiency (%)

In this part of the report, the efficiency results for all the motors in this study are illustrated in the form of the bar chart. The efficiency of the motor is calculated manually from the obtained results of the output power and the input power.

The plot shows the percentage efficiency of all the motors taken in this study. And evaluated for the better performance.

Fig 36 Efficiency plots at no-load and Full load.

From the results of the efficiency it can be noticed that the new developed models are having around 10% of increment in the efficiency. The efficiency of the induction motor is noted 78% at full load operation. So, there is the noticeable change in the efficiency noted and the losses are also decreased. So, from the overall comparison the Line-start synchronous reluctance motor and the line-start permanent magnet synchronous reluctance motor outperform the commonly used induction motor. But, in the no-load efficiency the load is set to 0Nm. And in the, plots it shows some losses. But, by looking at the actual efficiency at no-load for all the machines is 0%. Which is shown in the fig 36.

At last the summary of all the motors used in this study is illustrated in the form of table 8 below.

Table 8, Summary of result comparison for all proposed models with benchmark induction motor.

	Induction Motor	LSSynRM (Hyperbolic curve)	LSSynRM (Hyperbolic line)	LSPMSynRM (Hyperbolic curve)	LSPMSynRM (Hyperbolic line)
Rated Output Power (kW)	20	20	20	20	20
Number of Poles	4	4	4	4	4
Speed (rpm)	1465	1500	1500	1499	1500
Frequency (Hz)	50	50	50	50	50
Power Factor	0.96	0.96	0.96	0.97	0.97
Efficiency (%)	78.2	86.9	83	88.75	88
Losses (W)	161.17	149.075	152.77	146.94	148
Permanent Magnet	-	-	-	Yes	Yes
Material of Magnet	-	-	-	NdFe35	NdFe35
Airgap	0.55	0.55	0.55	0.55	0.55
Cage Type	Double cage	Aluminium accommodated in Flux barriers	Aluminium accommodated in Flux barriers	Aluminium accommodated in Flux barriers	Aluminium accommodated in Flux barriers

5.8 Fan Type Load

Fig 37 shows the speed vs time response for the fan type load for all the motors. Here, the motors are tested with the fan type load, where the load torque is proportional to the square of the speed. The equation for the fan load is illustrated below.

$$T=TL\left(\frac{Speed}{Synchronous\ speed}\right)^2 Nm$$

Fig 37 Speed vs Time (Fan type load).

From the fig it is noticed that the induction motor reached to 1465 rpm and the line-start synchronous reluctance motor reach to the speed of 1500 rpm after 300ms. Also, the line-start permanent magnet synchronous reluctance motor reaches to 1500 rpm. So, from this response it can be noticed that the induction motor takes less time to reach at the constant speed. So, induction motor has the better dynamic performance for the fan type load compared to the other motors.

But, from all the different test it has been noticed that the proposed models are giving better performance and compared to induction motor in the loading condition in terms of efficiency.

Chapter 6

Conclusion and Future Work

6.1 Conclusion

In this chapter of the report the conclusion is made with respect to the result. So, in the first chapter of the report, the importance of the developing the efficient motor is studied and the overall worldwide consumption of the electricity by electric motor was focused. And the special focus in that chapter is on the consumption of electricity in Australia and New-Zealand and because of the losses in the electric motors the emission of CO₂ is taken in to account. So, from the first chapter the necessity of developing efficient motor is understood and, the statistics of the world got to know from the carried-out study. The first chapter also conclude the problem statement, which includes the reason for the lower efficiency in the induction motor. Also, advantages of the synchronous reluctance motor over the induction motor. These concludes the idea of designing the hybrid design of the motor.

Secondly, with the help of literature review, several researches and the obtained results were studied. In addition to that, Different designing methods of electrical machines are got familiarized. The previous researches also contribute in the development of the knowledge for designing the electrical machine and various design aspects were studied. Also, the gap was notified that, most of the researches were based on the synchronous reluctance motor and the permanent magnet synchronous reluctance motor which gives an idea for combining the features of the permanent magnet and line-start capability.

In the next chapter of the design aspects, the study of the benchmark three-phase induction motor was carried out. In this chapter, the induction motor was designed with the referenced parameters in Maxwell 2D. And the various parameters selection is learnt from this design. Also, it includes the design of additional four design of the line-start synchronous reluctance motor with and without magnets were created. While designing there are several complications were faced because of the beginner level of the software. And with the help of online tutorials and available vast amount of the audio-visual resources the knowledge of designing is developed. Also, the approximation of the barriers from the flux-lines on the solid core was carried out for cutting the air barriers and the approximation for the accommodation of cage in the rotor. This chapter was concluded with the fine design of the proposed models of the motor.

From the simulation part of the project, the simulation procedure for obtaining various of the results were learnt. The importance of the time steps and the parameters optimization is also understood. Also, with the help of finite element analysis, the magnetostatic analysis was carried out and the magnetic circuit of the machine, flux density, flux linkage and optimization of the magnetic flux density was derived and understood. Also, the application of the mechanical load as well as the derivation of different results in the form of graphs is learnt. In the magnetostatic analysis the flux density and the flux line represents the concertation of the flux distributed on the surface of the rotor and stator which is found 4.00 wb/m is reasonable for the motor.

Result and discussion part of this report concludes that as the mass of the rotor decrease the rotor losses

got decreases and as a result the efficiency of the machine increased. Because of the hybrid arrangement of the cage and the synchronous reluctance motor the newly developed line-start synchronous reluctance motor and line-start permanent synchronous reluctance motor achieved the line-start capability as an induction motor. So, from the plots in the start-up of the motor it can be clearly concluded that the developed models reach 1500 rpm so, in the developed models matches the results obtained from the benchmark induction motor. So, it can be concluded that the developed models are successful to achieve the self-starting capability. Also, the torque density of the developed models is increased and due to the better torque density, these line-start permanent magnet synchronous reluctance motors are suitable for the industrial application.

In addition, the winding currents were noticed flowing smoothly throughout the motor. In the starting of the motor the higher current drops. But, as the motor start rotating gradually the current plots become stable and smooth. The losses in the new developed models are noticed less than the benchmark model of an induction motor. So, as the losses are decreased the efficiency of the motor got increased. And because of adding the magnets the torque density and the efficiency is also improved. Also, it causes lower thermal resistance and clean operation. For all the no-load operation, the efficiency of the motor was notified as 0%. Because of 0Nm of load torque, which results output power to be zero. From the efficiency plot of all the machines clearly shows the increment in the efficiency as the models got modified. So, from the results it can be clearly seen that the proposed design can replace the induction motor in terms of the performance. Also, the fan type load was applied to check the start-up of the motor. In that test, the induction motor is getting nearly constant speed earlier than the other models. So, for the fan type load means in the less loading condition the induction motor is getting advantage. But, in the high loading condition such as in the industrial environment the developed models can be better than the induction motor. In addition to that, the magnet used are not extremely expensive as rare earth magnets. And due to the less material consumption, the construction of this motor can be economical same as an induction motor. Also, for all the designed models the power factor is noticed below unity and the efficiency got increased gradually.

So, the newly designed models can replace the widely-used induction motor in terms of performance and as an economical alternative because of its better efficiency and several more advantages in terms of torque density, low production cost, better output power and simple construction.

In addition to that, there are not much researches carried out on this type of the design of the machine. And the carried-out tests are not limited to check the performance of the machine. So, there are various areas to expand this project for getting more better performance and better optimization of the design, which is illustrated below in the next part.

6.2 Future work

Optimal changes with the design

Basically, this study focusses on the design of the line-start synchronous reluctance motor and line-start permanent magnet synchronous reluctance motor and the performance analysis of these both machines with the help of finite element method. But, for the future work in the research the shape of the magnets can be changed and optimized. Also, the orientation of the cage in the rotor can be re-developed with the different shape.

Analysis of the machine

In this research, it provides the results of magneto static analysis, steady state analysis and transient analysis. In this analysis the speed, torque, winding currents, power factor, efficiency, input and output power, losses of the machine are studied and obtained for no load and full load. But, other analysis can be obtained for the harmonics of the motor, also the thermal analysis can be carried out as a future work.

Prototyping

In this study, the physical working models were not made. So, the prototyping of the motor can be done for the validation of the simulated results.

Further testing of the machine

The tests given and performed in this thesis were not comprehensive. There is more test, which can be performed on the motor. Such as, the strength of vibration, level of noise, thermal test. Furthermore, the performance of the motor can be observed with the pulse load and ramp load.

6. Input Power Vs Output Power vs time.

Output Power

Line-start Synchronous Reluctance Motor (Hyperbolic Curve) (20kW) (More than full load 137.38Nm)

1.Speed Vs Time.

2.Torque Vs Time.

3. Winding Currents Vs Time.

4. Torque Vs Speed

5. Losses (Core loss, hysteresis loss, eddy current loss)

6. Input Power, output Power vs time.

Output Power

Line-start Synchronous Reluctance Motor (Hyperbolic Line)(20kW)(More than full load 137.38Nm)

1.Speed Vs Time.

2.Torque Vs Time.

3. Winding Currents Vs Time.

4. Torque Vs Speed

5. Losses (Core loss, hysteresis loss, eddy current loss)

6. Input Power Vs output Power vs time.

Output Power

Output Power

Hyperbolic_line_Rotor 

Line-start Permanent Magnet Synchronous Reluctance Motor (Hyperbolic curve) (137.38Nm)

1. Speed Vs Time

2. Torque Vs time

3. Winding currents Vs time

4. Torque vs speed

5. Power Vs time

6. Losses Vs Time
